**Abstract:** We analyse the low temperature phase of ferromagnetic Kac-Ising models in dimensions $d \geq 2$. We show that if the range of interactions is $\gamma^{-1}$, then two disjoint translation invariant Gibbs states exist, if the inverse temperature $\beta$ satisfies $\beta - 1 \geq \gamma^\kappa$, where $\kappa = \frac{d(1-\epsilon)}{(2d+2)(d+1)}$, for any $\epsilon > 0$. The prove involves the blocking procedure usual for Kac models and also a contour representation for the resulting long-range (almost) continuous spin system which is suitable for the use of a variant of the Peierls argument.

# 1. Introduction

In 1963 Kac et al. [KUH] introduced a statistical mechanics model of particles interacting via long, but finite range interactions, i.e. through potentials of the form $J_\gamma(r) \equiv \gamma^d J(\gamma r)$, there $J$ is some function of bounded support or rapid decrease (the original example was $J(r) = e^{-r}$) and $\gamma$ is a small parameter. These models were introduced as microscopic models for the van der Waals theory of the liquid-gas transition. In fact, in the context of these models it proved possible to derive in a mathematically rigorous way the van der Waals theory including the Maxwell construction in the limit $\gamma \downarrow 0$. In mathematical terms, this is stated as the Lebowitz-Penrose theorem[LP]: The distribution of the density satisfies in the infinite volume limit a large deviation principle with a rate function that, in the limit as $\gamma$ tends to zero, converges to the convex hull of the van der Waals free energy. For a review of these results, see e.g. the textbook by Thompson [T].

Only rather recently there has been a more intense interest in the study of Kac models that went beyond the study of the global thermodynamic potentials in the Lebowitz-Penrose limit, but that also considers the distribution of *local mesoscopic* observables. This program has been carried out very nicely in the case of the Kac-Ising model in one spatial dimension by Cassandro, Orlandi, and Presutti [COP]. A closely related analysis had been performed earlier by Bolthausen and Schmock [BS]. These analysis can be seen as a rigorous derivation of a Ginzburg-Landau type field theory for these models. Very recently, such an analysis was also carried out in a disordered version of the Kac Ising model, the so-called Kac-Hopfield model by Bovier, Gayrard, and Picco [BGP1,BGP2].

An extension of this work to higher dimensional situations would of course be greatly desirable. This turns out to be not trivial and, surprisingly, even very elementary questions about the Kac model in $d \geq 2$ are unsolved. One of them is the natural conjecture that the critical inverse temperature $\beta_c(\gamma)$ in the Kac model should converge, as $\gamma \downarrow 0$, to the mean-field critical temperature. This conjecture can be found e.g. in a recent paper by Cassandro, Marra, and Presutti [CMP]. In that paper a lower bound $\beta_c(\gamma) \geq 1 + b\gamma^2 |\ln \gamma|$ is proven. A corresponding upper bound is only known in a very particular case where reflection positivity can be used [BFS].

In addressing this question one soon finds the reason for this unfortunate state of affairs. All the powerful modern methods for analyzing the low-temperature phases of statistical mechanics models, like low-temperature expansions and the Pirogov-Sinai theory, have been devised in view of models with short range (often nearest neighbor) interactions, with possible longer range parts treated as some nuisance that can be shown to be quite irrelevant. To deal with the genuinely long-range interaction in Kac models, that is to exploit their long range nature, these methods require substantial adaptation. The purpose of the present paper is to help to develop adequate techniques to deal with this problem – that beyond proving the conjecture of [CMP] will, hopefully, also provide a basis for the analysis of disordered Kac models. (Together with possible other means not touched by the presented article : most notably with suitably developed expansion techniques for long range models).

The model we consider is defined as follows. We consider a measure space $(\mathcal{S}, \mathcal{F})$ where $\mathcal{S} \equiv \{-1, 1\}^{\mathbb{Z}^d}$ is equipped with the product topology of the discrete topology on $\{-1, 1\}$ and $\mathcal{F}$ is the corresponding finitely generated sigma-algebra. We denote an element of $\mathcal{S}$ by $\sigma$ and call it a spin-configuration. If $\Lambda \subset \mathbb{Z}^d$, we denote by $\sigma_\Lambda$ the restriction of $\sigma$ to $\Lambda$. For any finite volume $\Lambda$ we define the energy of the configuration $\sigma_\Lambda$ (given the external configuration $\sigma_{\Lambda^c}$) as

$$H_{\gamma,\Lambda}(\sigma_\Lambda, \sigma_{\Lambda^c}) \equiv -\tfrac{1}{2} \sum_{i,j \in \Lambda, j \in \mathbb{Z}^d} J_\gamma(i-j)\sigma_i\sigma_j - \sum_{i \in \Lambda, j \notin \Lambda} J_\gamma(i-j)\sigma_i\sigma_j \qquad (1.1)$$

where $J_\gamma(i) \equiv \gamma^d J(\gamma i)$ and $J : \mathbb{R}^d \to \mathbb{R}$ is a function that satisfies $\int_{\mathbb{R}^d} dx J(x) = 1$. For simplicity we will assume that $J$ has bounded support, but the extension of our proof to more moderate assumptions on the decay properties of $J$ is apparently not too difficult. To be completely specific we will even choose $J(r) \equiv c_d \mathbb{I}_{|x| \leq 1}$ where $c_d$ normalizes the integral of $J$ to one[1]. Here $|\cdot|$ is most conveniently chosen as the sup-norm on $\mathbb{R}^d$.

Finite volume Gibbs measures ("local specifications") are defined as usual as

$$\mu^\eta_{\gamma,\beta,\Lambda}(\sigma_\Lambda) \equiv \frac{1}{Z^\eta_{\gamma,\beta,\Lambda}} e^{-\beta H_{\gamma,\Lambda}(\sigma_\Lambda, \eta_{\Lambda^c})} \qquad (1.2)$$

where $Z^\eta_{\gamma,\beta,\Lambda}$ is the usual partition function. Note that under our assumptions on $J$ the local specifications for given $\Lambda$ depend only on finitely many coordinates of $\eta$. An infinite volume Gibbs state $\mu_{\gamma,\beta}$ is a probability measure on $(\mathcal{S}, \mathcal{F})$ that satisfies the DLR-equations

$$\mu_{\gamma,\beta}\mu_{\gamma,\beta,\Lambda} = \mu_{\gamma,\beta} \qquad (1.3)$$

Our first result will be the following

---

[1] The generic name $c_d$ will be used in the sequel for various finite, positive constants that only depend on dimension.

**Theorem 1:**   *Let $d \geq 2$. Then there exists a function $f(\gamma)$ with $\lim_{\gamma \downarrow 0} f(\gamma) = 0$ such that for all $\beta > 1 + f(\gamma)$, there exist at least two disjoint extremal infinite volume Gibbs states with local specifications given by (1.2). Moreover, for $\gamma$ small enough, $f(\gamma) \leq \gamma^{\frac{1-\epsilon}{(2d+2)(1+1/d)}}$ for arbitrary $\epsilon > 0$*

**Remark:** This theorem shows that the conjecture of [CMP] is correct. Together with Theorem 1 of [CMP] it implies that $\lim_{\gamma \downarrow 0} \beta_c(\gamma) = 1$ in the Kac model. While completing this work we have received a paper by M. Cassandro and E. Presutti [CP] in which the conjecture of [CMP] is also proven, but no explicit estimate on the asymptotics of the function $f(\gamma)$ is given. Their proof is rather different from ours. Although at the moment we make use of the spin flip symmetry of the model, the contour language we introduce is also intended as a preparatory step for future use of the Pirogov-Sinai theory for non-symmetric long range models.

We will in fact get more precise information on the infinite volume Gibbs measures in the course of the proof. This will be expressed in terms of the distribution of "local magnetization", $m_x(\sigma)$, defined on some suitable length scale $1 \ll \ell \ll \gamma^{-1}$. Given such scale $\ell$, we will partition the lattice $\mathbb{Z}^d$ into blocks, denoted by $x$ of side length $\ell$. We set Identifying the block $x$ with its label $x \in \mathbb{Z}$, we could thus set

$$x \equiv \{i \in \mathbb{Z}^d \mid |i - \ell x| \leq \ell/2\} \tag{1.4}$$

We then define

$$m_x(\sigma) \equiv \frac{1}{\ell} \sum_{i \in x} \sigma_i \tag{1.5}$$

In the sequel we will assume that all finite volumes we consider are compatible with these blocks, that is are decomposable into them. We will also assume that $\gamma \ell$ is an integer. For any volume $\Lambda$ compatible with the block structure, we denote by $\mathcal{M}_\Lambda \subset \mathcal{F}_\Lambda$ the sigma-algebra generated by the family of variables $\{m_x(\sigma)\}_{x \in \Lambda}$. The block variables will be instrumental in the proof of Theorem 1. However, they are also the natural variables to characterize the nature of typical configurations w.r.t. the Gibbs measure. We should note that this first step of passing to the variables $m_x(\sigma)$ is also used in [CP], in fact it is used in virtually all work on the Kac model.

The remainder of this article is organized as follows. In Section 2 the distribution of the block spins are formally introduced and the block-spin approximation of the Hamiltonian is discussed. In Section 3 we introduce our notion of Peierls contours and prove our theorem through variant of the Peierls argument [P].

## 2. Block spin approximation

All the questions we want to answer in our model will after all concern the probabilities of events that are elements of the sigma-algebras $\mathcal{M}_V$ for finite volumes $V$. If $\mathcal{A} \in \mathcal{M}_V$ is such an event and $\Lambda \supset V$, we have the following useful identity

$$
\begin{aligned}
\mu_{\gamma,\beta,\Lambda}^{\eta}(\mathcal{A}) &= \sum_{\sigma_{\Lambda\backslash V}} \mu_{\gamma,\beta,\Lambda}^{\eta}(\sigma_{\Lambda\backslash V}) \mu_{\gamma,\beta,V}^{\sigma_{\Lambda\backslash V},\eta_{\Lambda^c}}(\mathcal{A}) \\
&= \sum_{\sigma_{\Lambda\backslash V}} \mu_{\gamma,\beta,\Lambda}^{\eta}(\sigma_{\Lambda\backslash V}) \sum_{\substack{m_x, x \in V \\ \{m_x\} \subset \mathcal{A}}} \mu_{\gamma,\beta,V}^{\sigma_{\Lambda\backslash V},\eta_{\Lambda^c}}(\{m_x\}_{x\in V})
\end{aligned}
\tag{2.1}
$$

The sum over $m_x$ runs of course over the values $\{-1, -1 + 2\ell^{-d}, \ldots, 1 - 2\ell^{-d}, 1\}$ Note that we may, if $J$ has compact support, assume without loss of generality that $\Lambda$ is sufficiently large so that the local specification $\mu_{\gamma,\beta,V}^{\sigma_{\Lambda\backslash V},\eta_{\Lambda^c}}$ does not depend on $\eta$. We will therefore drop the $\eta$ in this expression.

The main point which makes the Kac-model special, is that the Hamiltonian is "close" to a function of the block spins. Namely, we may write

$$
\begin{aligned}
H_{\gamma,V}(\sigma_V, \sigma_{V^c}) &= -\tfrac{1}{2}\sum_{x,y\in V}\sum_{i\in x, j\in y} J_\gamma(i,j)\sigma_i\sigma_j - \sum_{x\in V, y\in V^c}\sum_{i\in x, j\in y} J_\gamma(i,j)\sigma_i\sigma_j \\
&= -\tfrac{1}{2}\sum_{x,y\in V} J_\gamma(\ell(x-y)) \sum_{i\in x, j\in y} \sigma_i\sigma_j \\
&\quad - \sum_{x\in V, y\in V^c} J_\gamma(\ell(x-y)) \sum_{i\in x, j\in y} \sigma_i\sigma_j \\
&\quad - \tfrac{1}{2}\sum_{x,y\in V}\sum_{i\in x, j\in y} [J_\gamma(i-j) - J_\gamma(\ell(x-y))] \sigma_i\sigma_j \\
&= H_{\gamma,\ell,V}^{(0)}(m_V(\sigma_V), m_{V^c}(\sigma_{V^c})) + \Delta H_{\gamma,\ell,V}(\sigma_V, \sigma_{V^c})
\end{aligned}
\tag{2.2}
$$

where we have set (recall that $J_\gamma(\ell x) = \ell^{-d} J_{\ell\gamma}(x)$)

$$
H_{\gamma,\ell,V}^{(0)}(m_V, m_{V^c}) \equiv -\ell^d \tfrac{1}{2}\sum_{x,y\in V} J_{\gamma\ell}(x-y) m_x m_y - \ell^d \sum_{x\in V, y\in V^c} J_{\gamma\ell}(x-y) m_x m_y
\tag{2.3}
$$

and

$$
\begin{aligned}
\Delta H_{\gamma,\ell,V}(\sigma_V, \sigma_{V^c}) &= -\tfrac{1}{2}\sum_{x,y\in V}\sum_{i\in x, j\in y} [J_\gamma(i-j) - J_\gamma(\ell(x-y))] \sigma_i\sigma_j \\
&\quad - \sum_{x\in V, y\in V^c}\sum_{i\in x, j\in y} [J_\gamma(i-j) - J_\gamma(\ell(x-y))] \sigma_i\sigma_j
\end{aligned}
\tag{2.4}
$$

4

**Lemma 2.1:** *For any $V \subset \mathbb{Z}^d$,*

$$\sup_\sigma |\Delta H_{\gamma,\ell,V}(\sigma_V, \sigma_{V^c})| \leq c_d \gamma \ell |V| \tag{2.5}$$

*where $c_d$ is some numerical constant that depends only on the dimension $d$.*

**Proof:** This fact is well-known and simple for all Kac models. In our case it follows from the observation that $[J_\gamma(i-j) - J_\gamma(\ell(x-y))] = 0$, unless $|x-y| \approx 1/(\gamma\ell).\diamond$

As consequence of Lemma 2.1 we get the following useful upper and lower bounds for the distribution of the block spins:

$$\mu_{\gamma,\beta,V}^{\sigma_{\Lambda \backslash V}}(m_V) \begin{array}{c} < \\ > \end{array} \frac{e^{-\beta \ell^d H_{\gamma,\ell,V}^{(0)}(m_V, m_{V^c})} \prod_{x \in V} \mathbb{E}_\sigma \mathbb{1}_{m_x(\sigma)=m_x}}{\sum_{m_V} e^{-\beta \ell^d H_{\gamma,\ell,V}^{(0)}(m_V, m_{V^c})} \prod_{x \in V} \mathbb{E}_\sigma \mathbb{1}_{m_x(\sigma)=m_x}} e^{\pm \beta c_d \gamma \ell |V|} \tag{2.6}$$

Of course

$$\mathbb{E}_\sigma \mathbb{1}_{m_x(\sigma)=m_x} \begin{cases} 2^{-\ell^d} \left(\frac{\ell^d}{\frac{1+m_x}{2}\ell^d}\right), & \text{if } \ell^d/m_x/2 \in \mathbb{Z} \\ 0, & \text{else} \end{cases} \tag{2.7}$$

and thus, by Sterling's formula,

$$2^{-\ell^d} \left(\frac{\ell^d}{\frac{1+m_x \ell^d}{2}\ell^d}\right) = e^{-\ell^d I(m_x) + O(\ln \ell)} \tag{2.8}$$

where $I(m)$, for $m \in [-1,1]$ is

$$I(m) = \frac{1+m}{2} \ln(1+m) + \frac{1-m}{2} \ln(1-m) \tag{2.9}$$

Therefore we define

$$E_{\gamma,\beta,\ell,V}(m_V, m_{V^c}) \equiv -\frac{1}{2} \sum_{x,y \in V} J_{\gamma\ell}(x-y) m_x m_y - \sum_{x \in V, y \in V^c} J_{\gamma\ell}(x-y) m_x m_y + \beta^{-1} \sum_{x \in V} I(m_x) \tag{2.10}$$

to get

**Lemma 2.2:** *For any finite volume $V$ and any configuration $m_V$, we have*

$$\mu_{\gamma,\beta,V}^{\sigma_{\Lambda \backslash V}}(m_V) \begin{array}{c} < \\ > \end{array} \frac{e^{-\beta \ell^d E_{\gamma,\beta,\ell,V}(m_V, m_{V^c}(\sigma_{V^c}))}}{\sum_{m_V} e^{-\beta \ell^d E_{\gamma,\beta,\ell,V}(m_V, m_{V^c}(\sigma_{V^c}))}} e^{\pm \beta c_d \gamma \ell |V|} \tag{2.11}$$

**Remark:** $\ell$ will be chosen as tending to infinity as $\gamma$ tends to zero. The idea is that that $E_{\gamma,\beta,\ell,V}$ is in a sense a "rate function"; that is to say, $E_{\gamma,\beta,\ell,V}$ alone determines the measure since the residual entropy is only of the order $\frac{d \ln \ell}{\ell^d}|V|$. The problem is that this is only meaningful when we consider events $\mathcal{A}$ for which the minimal $E_{\gamma,\beta,\ell,V}$ is of order $|V|$ above the ground state to make sure that

5

neither the residual entropy nor the error terms in (2.11) may invalidate the result. We will have to work in the next section to define such events.

It is instructive to rewrite the functional $E_{\gamma,\beta,\ell,V}$ in a slightly different form using that $-m_x m_y = \frac{1}{2}(m_x - m_y)^2 - \frac{1}{2}(m_x^2 + m_y^2)$ (we drop the indices $\gamma, \beta, \ell$ henceforth but keep this dependence in mind). We set

$$\widetilde{E}_V(m_V, m_{V^c}) \equiv \frac{1}{4} \sum_{x,y \in V} J_{\gamma\ell}(x-y)\,(m_x - m_y)^2 + \frac{1}{2} \sum_{x \in V, y \in V^c} J_{\gamma\ell}(x-y)\,(m_x - m_y)^2$$
$$+ \sum_{x \in V} f_\beta(m_x) \tag{2.12}$$

where $f_\beta$ is the well-known free energy function of the Curie-Weiss model,

$$f_\beta \equiv \left[ \beta^{-1} I(m_x) - \tfrac{1}{2} m_x^2 \right] \tag{2.13}$$

Then

$$E_V(m_V, m_{V^c}) = \widetilde{E}_V(m_V, m_{V^c}) - C_V(m_{V^c}) \tag{2.14}$$

where

$$C_V(m_{V^c}) \equiv \frac{1}{2} \sum_{x \in V, y \in V^c} J_{\gamma\ell}(x-y) m_y^2 \tag{2.15}$$

depends only on the variables on $V^c$.

The form $\widetilde{E}_V$ makes nicely evident the fact that the energy functional favours configurations that are constant and close to the minima of the Curie-Weiss function $f_\beta(m)$.

# 3. Peierls contours

In this Section we define an appropriate notion of Peierls-contours in our model and use this to proof Theorem 1 by a version of the Peierls argument[2]. The general spirit behind the definition of Peierls contours can be loosely characterized as follows: We want to define a family of local events that have the property that at least one of them has to occur, if the effect of boundary conditions does not propagate to the interior of the system. Then one must show that the probability that any of these events occurs is small. We will define such events in terms of the *block spin variables* $m_x(\sigma)$. More precisely, since it is crucial for us to exploit that the new interaction is still long

---

[2] While the proof of [CP] is also based on a Peierls argument, their definition of Peierls contours is completely different from ours.

range[3], contours will be defined in terms of the *local averages*, $\phi_x(m)$, and the *local variances*, $\psi_x(m)$, defined through

$$\phi_x(m) \equiv \sum_y J_{\gamma\ell}(x-y)m_y \tag{3.1}$$

$$\psi_x(m) \equiv \sum_y J_{\gamma\ell}(x-y)(m_y - \phi_y(m))^2 \tag{3.2}$$

Then define the sets

$$\widetilde{\underline{\Gamma}} \equiv \left\{ x \mid |\,|\phi_x(m)| - m^*(\beta)| > \zeta m^*(\beta) \quad \text{or} \quad \psi_x(m) > (\zeta m^*(\beta))^2 \right\} \tag{3.3}$$

where $m^*(\beta)$ is the largest solution of the equation $x = \tanh\beta x$, that is the location of the non-negative minimum of the function $f_\beta$. We recall (see e.g [E]) that $m^*(\beta) = 0$ if $\beta \leq 1$, $m^*(\beta) > 0$ if $\beta > 1$, $\lim_{\beta\uparrow\infty} m^*(\beta) = 1$ and $\lim_{\beta\downarrow 1} \frac{(m^*(\beta))^2}{3(\beta-1)} = 1$. To simplify notation we will write $m^* \equiv m^*(\beta)$ in the sequel. $\zeta, \hat{z} < 1$ will be chosen in a suitable way later. Note that if the boundary conditions are such that say $\phi_x(m(\eta)) \approx +m^*$, then, if the configuration near the origin is such that $\phi_0(m(\sigma) < 0$, there must be a region enclosing the origin on which $\phi$ takes the value zero and thus belongs to $\widetilde{\underline{\Gamma}}$. For a reason that will become clear later, in a first step we will regularize this set. For this we introduce a second blocking of the lattice, this time on the *scale of the range of the interaction*. The points $u$ of this lattice are identified with the blocks

$$u \equiv \left\{ x \in \mathbb{Z}^d \mid |x - u/(\gamma\ell)| \leq 1/(2\gamma\ell) \right\} \tag{3.4}$$

just as in (1.4). We write in a natural way $u(x)$ for the label of the unique block that contains $x$. We will call sets that are unions of such blocks $u$ *regular sets*. We put

$$\underline{\Gamma}_0 \equiv \left\{ x \mid u(x) \cap \widetilde{\underline{\Gamma}} \neq \emptyset \right\} \tag{3.5}$$

For some positive integer $n \geq 1$ to be chosen later, we now set

$$\underline{\Gamma} \equiv \left\{ x \mid \text{dist}(x, \underline{\Gamma}_0) \leq n(\gamma\ell)^{-1} \right\} \tag{3.6}$$

where *dist* is the metric induced by the sup-norm on $\mathbb{R}^d$. $n$ will depend on $\beta$ and diverge as $\beta \downarrow 1$. The precise value of $n$ will be specified later in (3.48). Notice that this definition assures that the set $\underline{\Gamma}$ is a regular set in the sense defined above.. Connected components of the set set $\underline{\Gamma}$ together with the specification of the values of $m_x$, $x \in \underline{\Gamma}$ are called contours and are denoted by $\Gamma$. For such a contour, we introduce the notion of its *boundary* $\partial\Gamma$, in the following sense:

$$\partial\Gamma \equiv \left\{ x \in \underline{\Gamma} \mid \text{dist}(x, \underline{\Gamma}^c) \leq n(\gamma\ell)^{-1} \right\} \tag{3.7}$$

---

[3] For that reason it is not possible to directly use the methods developed in [DZ] for studying low temperature phases of short range continuous spin models, although some of the ideas in that paper are used in our proof.

Note that by our definition of $\Gamma$ we are assured that $\partial\Gamma \cap \underline{\Gamma}_0 = \emptyset$. We denote by

$$D^{\pm} \equiv \{x \mid |\phi_x(m) \mp m^*| \leq \zeta m^*\} \cap \underline{\Gamma}^c \qquad (3.8)$$

and call these regions $\pm$-correct. Each connected component of the boundary of $\Gamma$ connects either to $D^+$ or $D^-$. We will denote such connected components by $\partial\Gamma_i^+$ and $\partial\Gamma_i^-$, respectively.

For a connected set $\underline{\Gamma}$ we denote by $\mathrm{int}\,\underline{\Gamma}$ the simply connected set obtained by "filling up the holes" of $\underline{\Gamma}$. This set is called the interior of a contour. The boundary of $\mathrm{int}\,\underline{\Gamma}$ will be referred to as the exterior boundary of $\underline{\Gamma}$. The connected component of $\partial\Gamma$ that is also the boundary of $\mathrm{int}\,\underline{\Gamma}$ will be called exterior boundary of $\Gamma$ and denoted by $\partial\Gamma^{ext}$.

The strategy to prove Theorem 1 is the usual one. First we observe that if boundary conditions are strongly plus, then in order to have that, say, $|\phi_0(m) - m^*| > \zeta m^*$, it must be true that there exists a contour $\Gamma$ such that $0 \in \mathrm{int}\,\underline{\Gamma}$. Thus it suffices to prove that the probability of contours is sufficiently small. This will require a *lower bound* on the energy of *any configuration compatible with the existence of* $\underline{\Gamma}$, and an *upper bound* on a carefully chosen *reference configuration* in which the contour is absent. We will show later (Lemma 3.8) that a lower bound on the energy can easily be given in terms of the functions $\phi$ and $\psi$, a fact that motivates the definition of $\widetilde{\underline{\Gamma}}$. The long range nature of the interaction and the fact that the $m_x$ are essentially continuous variables require the construction of the extensive "safety belts" around this set in order to assure an effective decoupling of the core of a contour from its exterior. The crucial reason for the definition of contours through the nonlocal functions $\phi$ and $\psi$ is however the fact that these are "slowly varying" functions of $x$ for any configuration $m$. Therefore, even if the core $\widetilde{\underline{\Gamma}}$ is very "thin" (e.g. a single point), one can show that on a much larger set $|\phi_0(m) - m^*|$ or $\psi_x(m)$ must still be quite large (e.g. half of what is asked for in $\widetilde{\underline{\Gamma}}$). This guarantees that in spite of the very thick "safety belts" we must construct around $\widetilde{\underline{\Gamma}}$, the energy of a contour compares nicely with its volume $|\underline{\Gamma}|$.

We will now establish the "decoupling" properties. For this we must establish some properties of the configuration $m$ on $\partial\Gamma$ that minimizes $E_{\partial\Gamma}$ for given boundary conditions.

**Definition 3.1:** *A configuration $m_V^{opt}$ is called optimal if $m^{opt}$ minimizes $E_V(m_V, m_{V^c})$ for a given configuration $m_{V^c}$.*

An important point is that away from $\widetilde{\underline{\Gamma}}$, due to our definition of contours configurations must be close to constant in the following sense:

**Lemma 3.2:** *Assume that $\mathrm{dist}(x, \widetilde{\underline{\Gamma}}) > 1/(\gamma\ell)$. Then*

*(i)*

$$\sum_y J_{\gamma\ell}(x - y)\,(m_y \pm m^*)^2 \leq 4\zeta^2(m^*)^2 \qquad (3.9)$$

8

*and*

*(ii) for any $V \subset \widetilde{\underline{\Gamma}}$*

$$\sum_{y \in V} J_{\gamma \ell}(x - y)|m_y \pm m^*| \leq 2\zeta m^* \sqrt{\sum_{y \in V} J_{\gamma \ell}(x - y)} \qquad (3.10)$$

*where the sign depends on whether $\phi_x(m)$ is positive or negative in the region.*

**Proof:** The proof of (3.9) is straightforward from the definition of $\widetilde{\underline{\Gamma}}$ in (3.3) and (3.10) follows from (3.9) by the Schwartz inequality. $\Diamond$

We will now establish properties of an optimal configuration on regular sets with boundary conditions that satisfy properties (3.9) and (3.10).

**Lemma 3.3:** *Let $V$ be a regular set. Then there exists $\zeta_d > 0$ depending only on the dimension $d$ such that if $m_{V^c}$ is a boundary conditions of $+$ type for which (3.9) and (3.10) hold with $\zeta \leq \zeta_d$, then for all $x \in V$, $|m_x^{opt} - m^*| \leq m^*/2$. The corresponding statement holds for $-$ type boundary conditions.*

**Proof:** We see from (2.10) that we must have[4] for $y \in V$

$$0 = \frac{d}{dm_y} E_V(m_V, m_{V^c}) = \beta^{-1} I'(m_y) - \phi_y(m) \qquad (3.11)$$

(3.11) can be written as

$$m_y = \tanh\left(\beta \phi_y(m)\right) \qquad (3.12)$$

We may tacitly assume that $\phi_y(m)$ is positive (this assumption will be shown to be consistent). Since $m^*$ is a stable fixpoint of the function $\tanh \beta m$ that attracts all points on the positive half line, it follows that $|\tanh\left(\beta \phi_y(m)\right) - m^*| \leq |\phi_y(m) - m^*|$ and in particular, if $\phi_y(m) < m^*$, $\tanh\left(\beta \phi_y(m)\right) > \phi_y(m)$, while for $\phi_y(m) > m^*$, $\tanh\left(\beta \phi_y(m)\right) < \phi_y(m)$. We will first show that $m_x^{opt} \geq m^*/2$. Let $x \in V$ denote a point where

$$m_x = \inf_{y \in V}\left\{m_y \, | m_y \leq m^*\right\} \qquad (3.13)$$

If $m_x = m^*$, there is nothing to proof. But if $m_x < m^*$, then (3.13) can only be satisfied if $\text{dist}(x, \partial V) < 1/(\gamma \ell)$. For such points we can write

$$m_x - m^* \geq \sum_{y \in V} J_{\gamma \ell}(x - y)(m_y - m^*) + \sum_{y \in V^c} J_{\gamma \ell}(x - y)(m_y - m^*)$$

$$\geq (m_x - m^*) \sum_{y \in V} J_{\gamma \ell}(x - y) - 2\zeta m^* \sqrt{\sum_{y \in V^c} J_{\gamma \ell}(x - y)} \qquad (3.14)$$

---

[4] We ignore the fact that $m_x$ takes only discrete values and look for the optimal solution in the space of real-valued $m$. The point is that given such a solution, a discrete valued approximation can be constructed that differs in energy by less than $|\underline{\Gamma}|/\ell^d$ which is negligibly small.

where the second line follows by (3.10). Hence

$$m_x - m^* \geq -\frac{2\zeta m^*}{\sqrt{\sum_{y \in V^c} J_{\gamma\ell}(x-y)}} \tag{3.15}$$

On the other hand, (3.14) holds for any other point $y \in V$ as well, and inserting this into the first line of (3.14) we get

$$m_x - m^* \geq (m_x - m^*) \sum_{y \in V} \sum_{z \in V} J_{\gamma\ell}(x-y) J_{\gamma\ell}(y-z) - 4\zeta m^* \tag{3.16}$$

Clearly we have won if either

$$1 - \sum_{y \in V} \sum_{z \in V} J_{\gamma\ell}(x-y) J_{\gamma\ell}(y-z) \geq 8\zeta \tag{3.17}$$

or

$$\sqrt{\sum_{y \in V^c} J_{\gamma\ell}(x-y)} \geq 4\zeta \tag{3.18}$$

Due to the fact that $V$ is composed of cubes of sidelength of the range of the interaction, this follows from simple considerations if $\zeta$ is smaller than some dimension dependent constant. (Here is the reason for our definition of $\underline{\Gamma}_0$). In fact,

$$1 - \sum_{y \in V} \sum_{z \in V} J_{\gamma\ell}(x-y) J_{\gamma\ell}(y-z) = \sum_{y \in V^c} J_{\gamma\ell}(x-y) + \sum_{y \in V} \sum_{z \in V^c} J_{\gamma\ell}(x-y) J_{\gamma\ell}(y-z) \tag{3.19}$$

The point is that the second term on the right hand side of (3.19) cannot be too small as long as $\text{dist}(x, V^c) \leq 1/(\gamma\ell)$, for regular $V$ (if $V$ is *not* regular, this statement does not hold, of course; just consider a thin long spike entering into $V$ and let $x$ be near the tip of the spike!). In fact, the worst situation here occurs if $x$ is at a distance $r/(\gamma\ell)$ from a "corner" of $V^c$. One easily verifies that even in this case

$$\begin{aligned}
\sum_{y \in V} \sum_{z \in V^c} J_{\gamma\ell}(x-y) J_{\gamma\ell}(y-z) &\geq 2^{-(d+1)} \int_0^1 ds\, (r+s)^{d-1}(1-s)^d \\
&\geq 2^{-(d+1)} \int_0^1 ds\, s^{d-1}(1-s)^d = 2^{-(d+2)} \frac{((d-1)!)^2}{(2d-1)!}
\end{aligned} \tag{3.20}$$

so that (3.18) is verified if $4\zeta$ is smaller than this number. The numerical value of that bound can of course be improved, but we do not seek to do that.

Having established that $m_x \geq m^*/2$ in $V$, a trivial computation shows that our starting assumption that $\phi_x(m) > 0$ is also verified. Thus we have proven that $m_x^{opt} \geq m^*/2$. In the same way one shows also that $m_x^{opt} \leq 3m^*/2$ which concludes the proof of the lemma. $\diamondsuit$

10

In the sequel the notion of $n$-layer set defined in the following definition will be convenient.

**Definition 3.4:**  *A regular set $V$ is called a $n$-layer annulus, if there it is of the form*

$$V = \left\{ x \in \widetilde{V}^c \mid dist(x, \widetilde{V}) \leq n(\gamma \ell)^{-1} \right\} \tag{3.21}$$

*for some connected set $\widetilde{V}$ that is composed of blocks $u$. The sets*

$$V_k \equiv \left\{ x \in \widetilde{V}^c \mid (k-1)(\gamma \ell)^{-1} < dist(x, \widetilde{V}) \leq k(\gamma \ell)^{-1} \right\} \tag{3.22}$$

*are called the $k-th$ layers of $V$.*

Note that the sets $\partial \Gamma$ are by their definition $n$-layer sets.

We are interested in some properties of optimal configurations on $n$-layer sets. For this we will use the following simple fact about the function $f_\beta$, that may be found e.g. in [BG]

**Lemma 3.5:**  *Let $f_\beta(m) = \beta^{-1} I(m) - \frac{1}{2} m^2$. Then, for all $m \in [-1, 1]$*

$$f_\beta(m) - f_\beta(m^*) \geq c(\beta) \left( |m| - m^* \right)^2 \tag{3.23}$$

*where*

$$c(\beta) \equiv \frac{\ln \cosh(\beta m^*)}{\beta (m^*)^2} - \frac{1}{2} \tag{3.24}$$

*has the property that $c(\beta) > 0$ for all $\beta > 1$ and*

$$\lim_{\beta \downarrow 1} \frac{c(\beta)}{(m^*)^2} = \frac{1}{12} \tag{3.25}$$

From this we will derive the following Lemma (The analog of this Lemma for short range and purely quadratic Hamiltonians appeared already in [DZ]).

**Lemma 3.6:**  *Let $V$ be an $n$-layer set with $n \geq r/c(\beta)$. Then there exists a layer $V_k$ in $V$ such that*

$$\sum_{x \in V_k} \left( m_x^{opt} \right)^2 \leq 2^{-r} \frac{1}{8} (m^*)^2 (|V_1| + |V_n|) \tag{3.26}$$

**Proof:** Let us set $u_x \equiv |m_x| - m^*$ and and use the abbreviation

$$\| u_{V_k} \|_2^2 \equiv \sum_{x \in V_k} (u_x)^2 \tag{3.27}$$

and analogously for other functions. Then it is obvious from (2.12) that for any configuration,

$$\widetilde{E}_{V \setminus V_1 \setminus V_2} (m_{V \setminus V_1 \setminus V_n}, m_{V_1 \cup V_n}) \geq \sum_{k=2}^{n-1} c(\beta) \| u_{V_k} \|_2^2 + \sum_{x \in V \setminus V_1 \setminus V_n} f_\beta(m^*) \tag{3.28}$$

11

On the other hand, we may consider a configuration that equals $m^{opt}$ on $V_1$ and $V_n$ and has $m_x = m^*$ for all $x \in V \backslash V_1 \backslash V_n$. For this configuration

$$\widetilde{E}_{V \backslash V_1 \backslash V_2}(m_{V \backslash V_1 \backslash V_n} = m^*, m^{opt}_{V_1 \cup V_n}) = \frac{1}{2} \sum_{\substack{x \in V \backslash V_1 \backslash V_n \\ y \in V_1 \cup V_n}} J_{\gamma \ell}(x - y) \left( m^{opt}_y - m^* \right)^2 + \sum_{x \in V \backslash V_n} f_\beta(m^*)$$

(3.29)

By the definition of $m^{opt}$, it must thus be true that

$$0 \geq \widetilde{E}_{V \backslash V_1 \backslash V_2}(m^{opt}_{V \backslash V_1 \backslash V_n}, m^{opt}_{V_1 \cup V_n}) - \widetilde{E}_{V \backslash V_1 \backslash V_2}(m^{opt}_{V \backslash V_1 \backslash V_n} = m^*, m^{opt}_{V_1 \cup V_n})$$

$$\geq \sum_{k=2}^{n-1} c(\beta) \|u_{V_k}\|_2^2 - \frac{1}{2} \sum_{\substack{x \in V \backslash V_1 \backslash V_n \\ y \in V_1 \cup V_n}} J_{\gamma \ell}(x - y) \left( m^{opt}_y - m^* \right)^2$$

(3.30)

$$\geq \sum_{k=2}^{n-1} c(\beta) \|u_{V_k}\|_2^2 - \frac{1}{2} \left( \|u^{opt}_{V-1}\|_2^2 + \|u^{opt}_{V_n}\|_2^2 \right)$$

Thus, for any $q < n/2$, we have

$$q c(\beta) \inf_{k=2}^{q+1} \left[ \|u^{opt}_{V_k}\|_2^2 + \|u^{opt}_{V_{n+1-k}}\|_2^2 \right] \leq \sum_{k=2}^{n-1} c(\beta) \left[ \|u^{opt}_{V_k}\|_2^2 + \|u^{opt}_{V_{n+1-k}}\|_2^2 \right] \leq \frac{1}{2} \|u^{opt}_{V_1}\|_2^2 + \frac{1}{2} \|u^{opt}_{V_1}\|_2^2 \quad (3.31)$$

from where

$$\inf_{k=2}^{q+1} \left[ \|u_{V_k}\|_2^2 + \|u_{V_{n+1-k}}\|_2^2 \right] \leq \frac{1}{2q c(\beta)} \left[ \|u^{opt}_{V_1}\|_2^2 + \|u^{opt}_{V_1}\|_2^2 \right]$$

(3.32)

If $q$ is chosen as the smallest integer greater than $1/c(\beta)$ this shows that there exist $2 \leq k \leq q+1$ such that

$$\left[ \|u_{V_k}\|_2^2 + \|u_{V_{n+1-k}}\|_2^2 \right] \leq \frac{1}{2} \left[ \|u^{opt}_{V_1}\|_2^2 + \|u^{opt}_{V_1}\|_2^2 \right]$$

(3.33)

Iterating this construction, and using that by Lemma 3.3

$$\frac{1}{2} \|u^{opt}_{V_1}\|_2^2 + \frac{1}{2} \|u^{opt}_{V_1}\|_2^2 \leq \frac{1}{8} (m^*)^2 \left( |V_1| + |V_n| \right)$$

(3.34)

we arrive at the assertion of the lemma. $\diamondsuit$

We are now ready to construct our reference configuration and give an upper bound on its energy. For given contour $\Gamma$ and compatible external configuration $m$ on $\underline{\Gamma}^c$ we call $m^{opt}$ the configuration on $\underline{\Gamma}$ that minimizes the energy for a given core $\underline{\underline{\Gamma}}$. Clearly such a configuration is also an optimal configuration on $\partial \Gamma$ in the sense of Definition 3.1. Thus by Lemma 3.2 we know that in each connected component $\partial \Gamma_i^\pm$ of the boundary of $\Gamma$ there exists a layer $\mathcal{L}_i^\pm$ of thickness $1/(\gamma \ell)$ in $\partial \Gamma_i^\pm$ such that $\|m^{opt}_\mathcal{L} \mp m^*\|_2^2 \leq 2^{-r} \frac{1}{8} (m^*)^2 \frac{1}{2} [|V_1(\partial \Gamma_i^\pm)| + |V_n(\partial \Gamma_i^\pm)|]$ For given $\mathcal{L}_i^\pm$ we decompose $\partial \Gamma_i^\pm$ into the two sets

$$\partial \Gamma_{i,in}^\pm \equiv \left\{ x \in \partial \Gamma_i^\pm \backslash \mathcal{L}_i^\pm \mid, \operatorname{dist}(x, D^\pm) > \operatorname{dist}(\mathcal{L}_i^\pm, D^\pm) \right\}$$

(3.35)

12

and

$$\partial\Gamma^\pm_{i,out} \equiv \partial\Gamma^\pm_i \backslash \partial\Gamma^\pm_{i,in} \tag{3.36}$$

Without loss of generality we assume that the exterior boundary of our contour is attached to the $+$-correct region. We now define the reference configuration $m^{ref}$

$$m^{ref}_x \equiv \begin{cases} m^{opt}_x, & \text{if } x \in \partial\Lambda^+_{i,out} \\ -m^{opt}_x, & \text{if } x \in \partial\Lambda^-_{i,out} \\ m^*, & \text{for all other } x \in \underline{\Gamma} \\ m_x, & \text{for } x \in D^+ \\ -m_x <, & \text{for } x \in D^- \end{cases} \tag{3.37}$$

**Lemma 3.7:** *Let $m^{ref}$ be defined in (3.37). Then for any compatible external configuration we have that .*

$$\widetilde{E}_{\underline{\Gamma}}\left(m^{ref}_{\underline{\Gamma}}, m^{ref}_{\underline{\Gamma}^c}\right) \leq \sum_{i,\pm} \widetilde{E}_{\partial\Gamma^\pm_{i,out}}\left(m^{opt}_{\partial\Gamma^\pm_{i,out}}, m_{\underline{\Gamma}^c}\right) + \sum_{i,\pm} 2^{-r}\tfrac{1}{8}(m^*)^2[|V_1(\partial\Gamma^\pm_i)| + |V_n(\partial\Gamma^\pm_i)|]$$
$$+ \sum_{x \in \underline{\Gamma}\backslash\partial\Gamma_{out}} f_\beta(m^*) \tag{3.38}$$

**Proof:** The proof of this estimate is obvious from the definition of $m^{ref}$ and Lemma 3.6. Note that in the terms $\widetilde{E}_{\partial\Gamma^\pm_{i,out}}\left(m_{\partial\Gamma^\pm_{i,out}}, m_{\underline{\Gamma}^c}\right)$ the interaction energy between $\partial\Gamma^\pm_{i,out}$ and $\partial\Gamma^\pm_{i,in}$ is not counted. $\diamondsuit$

Of course the configuration $m^{ref}$ does not contain the contour $\Gamma$. It remains to find a lower bound on the energy of any configuration $m$ that does contain a contour with given $\underline{\Gamma}$.

To do this, we use the following observation.

**Lemma 3.8:** *Let $U,V,W \subset \mathbb{Z}^d$ be any three disjoint sets such that for all $y \in U \cup W$, $\sum_{x \in U \cup W \cup V} J_{\gamma\ell}(x - y) = 1$. and for any $y \in U$ $\sum_{x \in U \cup W} J_{\gamma\ell}(x - y) = 1$ Then*

$$\widetilde{E}_{V \cup U \cup W}(m_{V \cup U \cup W}, m_{(V \cup U \cup W)^c}) \geq \tfrac{1}{4}\sum_{x \in U} \psi_x(m) + \tfrac{1}{2}\sum_{x \in U \cup W} [f_\beta(m_x) + f_\beta(\phi_x(m))]$$
$$+ \sum_{x \in V} f_\beta(m^*) \tag{3.39}$$

**Proof:** The proof of this lemma is a simple, but, mainly because of boundary effects, somewhat lengthy computation that we do not wish to reproduce here. To get the idea, note that in infinite

13

volume we have (formally)

$$-\tfrac{1}{2}\sum_{x,y} m_x m_y J_{\gamma\ell}(x-y) + \beta^{-1}\sum_x I(m_x)$$

$$= -\tfrac{1}{2}\sum_x m_x \phi_x(m) + \beta^{-1}\sum_x I(m_x) \tag{3.40}$$

$$= \sum_x \left[ \frac{(m_x - \phi_x(m))^2}{4} - \frac{m_x^2}{4} - \frac{(\phi_x(m))^2}{4} + \tfrac{1}{2}\beta^{-1}I(m_x) + \tfrac{1}{2}\beta^{-1}\phi_x(I(m)) \right]$$

where we have put $\phi_x(I(m)) = \sum_y J_{\gamma\ell}(x-y)I(m_y)$. The last line is obtained by inserting the identity $1 = \sum_y J_{\gamma\ell}(x-y)$ in the $I(m)$ term and changing the order of summation in the resulting double sum. Using the same trick for the first term in the last line of (3.40), and using that, since $I$ is a convex function, $\phi_x(I(m)) \geq I(\phi_x(m))$, one gets that

$$\sum_x \left[ \frac{1}{4}\psi_x(m) + \frac{1}{2}f_\beta(\phi_x(m)) + \frac{1}{2}f_\beta(m_x) \right] \tag{3.41}$$

is a lower bound for (3.40). Trying to repeat this computation in finite volume and carefully dealing with the boundary terms leads to the more complicated looking formula (3.39). ◊

The main point in the estimate (3.39) is that it allows to bound the energy of a configuration from below in terms of $\phi_x(m)$ and $\psi_x(m)$ alone. Namely, taking for $V$ and $U \cup W$ the layers $\mathcal{L}_i^\pm$ and the regions "within" $\mathcal{L}_i^\pm$, we see that for any configuration

$$\widetilde{E}_{\underline{\Gamma}}\left(m_{\underline{\Gamma}}, m_{\underline{\Gamma}^c}\right) \geq \sum_{i,\pm} \widetilde{E}_{\partial\Gamma_{i,out}^\pm}\left(m_{\partial\Gamma_{i,out}^\pm}, m_{\underline{\Gamma}^c}\right)$$

$$+ \tfrac{1}{2}\sum_{x \in \underline{\Gamma}\setminus\partial\Gamma_{out}} [f_\beta(\phi_x(m)) - f_\beta(m^*)] + \tfrac{1}{4}\sum_{\substack{x \in \underline{\Gamma}\setminus\partial\Gamma_{out} \\ dist(x,\partial\Gamma_{out})>1/(\gamma\ell)}} \psi_x(m) \tag{3.42}$$

$$+ \sum_{x \in \underline{\Gamma}\setminus\partial\Gamma_{out}} f_\beta(m^*)$$

Next we show that bot $\phi_x(m)$ and $\psi_x(m)$ has nice continuity properties.

**Lemma 3.9:** *There exists a finite constant $c_d$ depending only on the dimension $d$ such that for any contour $\Gamma$, if $\widehat{\underline{\Gamma}}$ denotes the set*

$$\widehat{\underline{\Gamma}} \equiv \left\{ y \mid dist(y, \widetilde{\underline{\Gamma}}) \leq \frac{(\zeta m^*)^2}{8c_d\gamma\ell} \right\} \tag{3.43}$$

*then for all $y \in \widehat{\underline{\Gamma}}$, $\big|\,|\phi_y(m)| - m^*\big| \geq \frac{\zeta m^*}{2}$, or $\psi_x(m) \geq \frac{(\zeta m^*)^2}{2}$.*

**Proof:** Since $|m_x| \leq 1$, it is a simple geometric fact that

$$|\phi_x(m) - \phi_y(m)| \leq c_d|x - y|\gamma\ell \tag{3.44}$$

and

$$|\psi_x(m) - \psi_y(m)| \le 4c_d|x - y|\gamma\ell \tag{3.45}$$

for some geometry dependent constant $c_d$. Since on $\widetilde{\underline{\Gamma}}$, $|\phi_x(m)| \ge \zeta m^*$ or $\psi_x(m) \ge (\zeta m^*)^2$, the assertion of the lemma follows. $\Diamond$

**Remark:** The estimates of Lemma 3.9 are very crude. We expect that they can be improved considerably.

A further simple geometric consideration shows on the other hand that $\widehat{\underline{\Gamma}}$ cannot be too small compared to $\underline{\Gamma}$, namely

**Lemma 3.10:** *There exists a numerical constant $c'_d$ depending only on the dimension $d$ such that for any contour $\Gamma$, we have that*

$$|\underline{\Gamma}| \le c'_d \frac{(n+1)^d}{(\zeta m^*)^{2d}}|\widehat{\underline{\Gamma}}| \tag{3.46}$$

**Proof:** Note that $\frac{|\underline{\Gamma}|}{|\widehat{\underline{\Gamma}}|}$ is maximal if $\widehat{\underline{\Gamma}}$ consists of a single point in which case (3.46) is obvious. $\Diamond$

Combining the upper bound on the energy of $m^{ref}$ from Lemma 3.7 with the lower bound (3.42) obtained from Lemma 3.8 applied for the optimal configuration, using the fact that that $E$ and $\widetilde{E}$ differ only by a constant that depends only on boundary conditions, and finally employing Lemma 3.10 we arrive at

**Proposition 3.11:** *Let $\Gamma = (\underline{\Gamma}, m)$ be a contour with fixed $\underline{\Gamma}$. Then there exists a reference configuration $m^{ref}$ in which $\Gamma$ does not occur such that*

$$E_{\underline{\Gamma}}(m_{\underline{\Gamma}}, m_{\underline{\Gamma}^c}) - E_{\underline{\Gamma}}\left(m_{\underline{\Gamma}}^{ref}, m_{\underline{\Gamma}^c}^{ref}\right) \ge \frac{1}{8}\frac{c(\beta)}{c_d}\frac{(\zeta m^*)^{2d+2}}{(n+1)^d}|\underline{\Gamma}| - \frac{1}{8}(m^*)^2 2^{-nc(\beta)}|\underline{\Gamma}| \tag{3.47}$$

*where $c_d$ is a finite dimension-dependent constant and $c(\beta)$ is the constant from (3.24).*

**Proof:** We bound $E_{\underline{\Gamma}}(m_{\underline{\Gamma}}, m_{\underline{\Gamma}^c})$ from below by the the the corresponding energy of the configuration $m$ of lowest energy for given $\underline{\Gamma}$; on the belt of the contour this provides a optimal configuration in the sense of Definition 3.1. The same configuration is used in the construction of $m^{ref}$. After the obvious cancelations and using (3.46) and the fact that $c(\beta) \le 1$, we get the assertion of the proposition. $\Diamond$

We must now begin to choose our parameters. We want the Peierls condition, i.e. that the coefficient of $|\underline{\Gamma}|$ in (3.47) is positive and as large as possible. The most convenient choice appears to choose $n$ in such a way that

$$2^{-nc(\beta)} = \frac{1}{2}\frac{c(\beta)(\zeta m^*)^{2d}}{c_d(n+1)^d} \tag{3.48}$$

15

Calling the solution[5] of this equation $n^*$, we get the Peierls estimate

$$E_{\underline{\Gamma}}\left(m_{\underline{\Gamma}}, m_{\underline{\Gamma}^c}\right) - E_{\underline{\Gamma}}\left(m_{\underline{\Gamma}}^{ref}, m_{\underline{\Gamma}^c}^{ref}\right) \geq \frac{1}{16} \frac{c(\beta)(\zeta m^*)^{2d+2}}{c_d(n+1)^d} \tag{3.49}$$

It is not difficult to verify that

$$n^* \leq C \frac{1}{c(\beta)} \ln \left[\frac{c(\beta)(\zeta m^*)^{2d}}{2c_d}\right] \tag{3.50}$$

for some numerical constant $C$, if $c(\beta)$ is sufficiently small.

This estimate on the energy difference will only be useful for us if it is large compared to the error terms arising from the block approximation. That is to say, we must make sure that

$$\frac{1}{16} \frac{c(\beta)(\zeta m^*)^{2d+2}}{c_d(n+1)^d} > c_d \gamma \ell \tag{3.51}$$

(the two $c_d$ in this formula are a priori not the same quantities). This gives a relation between temperature dependent quantities on the one hand and $\gamma \ell$ on the other. It does not impose any choice on the parameter $\ell$. This arises from the last condition, the comparison between the energy of a contour and the entropy, i.e. the number of configurations $m$ on $\underline{\Gamma}$ and of shapes $\underline{\Gamma}$ with fixed volume $|\underline{\Gamma}|$. Even the crudest estimate shows that this number is smaller than $\ell^{d|\underline{\Gamma}|} C^{d|\underline{\Gamma}|}$ so that (3.51) is complemented by the condition

$$\beta \ell^d \left[\frac{1}{16} \frac{c(\beta)(\zeta m^*)^{2d+2}}{c_d(n+1)^d} - c_d \gamma \ell\right] > d \ln \ell + \ln C \tag{3.52}$$

which requires $\ell$ to be sufficiently large. In fact we may choose $\ell$ as

$$\ell = \gamma^{-1} \frac{1}{c_d} \frac{1}{32} \frac{c(\beta)(\zeta m^*)^{2d+2}}{c_d(n+1)^d} \tag{3.53}$$

which inserted into (3.52) gives the final condition of $\beta$ in terms of $\gamma$. It is clear that for any $\beta > 1$, i.e. $c(\beta) > 0$ and $m^* > 0$, this condition can be verified by choosing $\gamma$ sufficiently small. Thus using Lemma 2.2 we proved the analog of the Peierl's argument here, namely that the probability of a given contour $\Gamma$ is smaller than $\exp(-c|\underline{\Gamma}||\ln \ell|)$ which in turn implies that the probability that the origin is in the interior of a contour is close to zero (in fact of the order $\exp(-c\beta n^d|\ln \ell|)$). Moreover, by inserting the asymptotic behaviour of $m^*$ and $c(\beta)$, one verifies easily that if we put

$$\beta - 1 = \gamma^{\frac{1-\epsilon}{(2d+2)(1+1/d)}} \tag{3.54}$$

for arbitrary $\epsilon > 0$, then (3.52) is verified when $\gamma$ is sufficiently small. This gives thus the claimed bound on the behaviour of the critical temperature as $\gamma$ tends to 0.

---

[5] By this we will of course understand the smallest integer larger than or equal to the "real" solution

This concludes the proof of Theorem 1.◇◇

**Remark:** Let us recall some consequences of what we have just proven: if $V$ denotes the union of the interiors of all the contours of a given configuration than the Gibbs probability of the event

$$\text{dist}(i, V^c) \geq r \qquad (3.55)$$

is independent of the choice of the point $i \in \mathbb{Z}^d$ and behaves like $\exp(-Cr)$ where $C = C(\beta, \gamma)$. This implies for example the following statement: The probability of the event that the support of all contours surrounding a given point is infinite is equal to zero. One could even refine such a statement, giving a more precise meaning to the intuitive idea that "almost all configurations (of the mesoscopic observables $m$) in the translation invariant + Gibbs ensemble have their local averages (in the sense of the variables $\phi_x(m)$) in the vicinity of $m^*$ except of some (rare, but uniformly distributed throughout the lattice) "islands". (This is the appropriate rephrasing of the statement in Sinai's book [S]).

# Weierstraß–Institut für Angewandte Analysis und Stochastik

**Preprints 1995**

211. Dmitry Ioffe: Extremality of the disordered state for the Ising model on general trees.

212. Stefan Seelecke: Equilibrium thermodynamics of pseudoelasticity and quasi-plasticity.

**Preprints 1996**

213. Björn Sandstede: Stability of $N$–fronts bifurcating from a twisted heteroclinic loop and an application to the FitzHugh–Nagumo equation.

214. Jürgen Sprekels, Songmu Zheng, Peicheng Zhu: Asymptotic behavior of the solutions to a Landau–Ginzburg system with viscosity for martensitic phase transitions in shape memory alloys.

215. Yuri I. Ingster: On some problems of hypothesis testing leading to infinitely divisible distributions.

216. Grigori N. Milstein: Evaluation of moment Lyapunov exponents for second order linear autonomous SDE.

217. Hans Günter Bothe: Shift spaces and attractors in non invertible horse shoes.

218. Gianfranco Chiocchia, Siegfried Prößdorf, Daniela Tordella: The lifting line equation for a curved wing in oscillatory motion.

219. Pavel Krejčí, Jürgen Sprekels: On a system of nonlinear PDE's with tempera-ture–dependent hysteresis in one–dimensional thermoplasticity.

220. Boris N. Khoromskij, Siegfried Prößdorf: Fast computations with the harmonic Poincaré–Steklov operators on nested refined meshes.

221. Anton Bovier, Véronique Gayrard: Distribution of overlap profiles in the one–dimensional Kac–Hopfield model.

222. Jürgen Sprekels, Dan Tiba: A duality–type method for the design of beams.

223. Wolfgang Dahmen, Bernd Kleemann, Siegfried Prößdorf, Reinhold Schneider: Multiscale methods for the solution of the Helmholtz and Laplace equation.

224. Herbert Gajewski, Annegret Glitzky, Jens Griepentrog, Rolf Hünlich, Hans–Christoph Kaiser, Joachim Rehberg, Holger Stephan, Wilfried Röpke, Hans Wenzel: Modellierung und Simulation von Bauelementen der Nano– und Optoelektronik.

225. Andreas Rathsfeld: A wavelet algorithm for the boundary element solution of a geodetic boundary value problem.

226. Sergej Rjasanow, Wolfgang Wagner: Numerical study of a stochastic weighted particle method for a model kinetic equation.

227. Alexander A. Gushchin: On an information–type inequality for the Hellinger process.

228. Dietmar Horn: Entwicklung einer Schnittstelle für einen DAE–Solver in der chemischen Verfahrenstechnik.

229. Oleg V. Lepski, Vladimir G. Spokoiny: Optimal pointwise adaptive methods in nonparametric estimation.

230. Bernd Kleemann, Andreas Rathsfeld, Reinhold Schneider: Multiscale methods for boundary integral equations and their application to boundary value problems in scattering theory and geodesy.

231. Jürgen Borchardt, Ludger Bruell, Friedrich Grund, Dietmar Horn, Frank Hubbuch, Tino Michael, Horst Sandmann, Robert Zeller: Numerische Lösung großer strukturierter DAE–Systeme der chemischen Prozeßsimulation.

232. Herbert Gajewski, Klaus Zacharias: Global behaviour of a reaction–diffusion system modelling chemotaxis.

233. Fréderic Guyard, Reiner Lauterbach: Forced symmetry breaking perturbations for periodic solutions.

234. Vladimir G. Spokoiny: Adaptive and spatially adaptive testing of a nonparametric hypothesis.

235. Georg Hebermehl, Rainer Schlundt, Horst Zscheile, Wolfgang Heinrich: Simulation of monolithic microwave integrated circuits.

236. Georg Hebermehl, Rainer Schlundt, Horst Zscheile, Wolfgang Heinrich: Improved numerical solutions for the simulation of monolithic microwave integrated circuits.

237. Pavel Krejčí, Jürgen Sprekels: Global solutions to a coupled parabolic-hyperbolic system with hysteresis in 1–d magnetoelasticity.

238. Georg Hebermehl, Friedrich–Karl Hübner: Portabilität und Adaption von Software der linearen Algebra für Distributed Memory Systeme.

239. Michael H. Neumann: Multivariate wavelet thresholding: a remedy against the curse of dimensionality?
