FROM ROUGH PATH ESTIMATES TO MULTILEVEL MONTE CARLO

CHRISTIAN BAYER, PETER K. FRIZ, SEBASTIAN RIEDEL, AND JOHN SCHÖNMAKERS

Abstract. Discrete approximations to solutions of stochastic differential equations are well-known to converge with “strong” rate 1/2. Such rates have played a key-role in Giles’ multilevel Monte Carlo method [Giles, Oper. Res. 2008] which gives a substantial reduction of the computational effort necessary for the evaluation of diffusion functionals. In the present article similar results are established for large classes of rough differential equations driven by Gaussian processes (including fractional Brownian motion with $H > 1/4$ as special case).

We consider implementable schemes for large classes of stochastic differential equations (SDEs)

\begin{equation}
\label{eq:1}
dY_t = V_0(Y_t) \, dt + \sum_{i=1}^d V_i(Y_t) \, dX_i(t)
\end{equation}

driven by multidimensional Gaussian signals, say $X = X_t(\omega) \in \mathbb{R}^d$. The interpretation of these equations is in Lyons’ rough path sense [LQ02, LCL07, FV10b]. This requires smoothness/boundedness conditions on the vector fields $V_0$ and $V \equiv (V_1, \ldots, V_d)$; for the sake of this introduction, the reader may assume bounded vector fields with bounded derivatives of all order (but we will be more specific later). This also requires a “natural” lift of $X(t, \omega)$ to a (random) rough path

$X_\cdot(\omega) = 1 + \sum_{i=1}^N \int_{0<s_1<\cdots<s_i} dX_{s_1}(\omega) \otimes \cdots \otimes dX_{s_i}(\omega),$

a situation fairly well understood, cf. [FV10b, Ch. 15] and the references therein. The reader not familiar with rough path theory may think of $Y$ as “Stratonovich” solution to (1). In fact, $Y$ is known to be the Wong-Zakai limit, obtained by replacing $X$ in (1) by piecewise-linear approximation followed by taking the mesh-to-zero limit.

We shall simplify the discussion by choosing $V_0 \equiv 0$ and using the short-hand notation

\begin{equation}
\label{eq:2}
dY = V(Y) \, dX.
\end{equation}

Of course, it would be easy to include equations of the form (1) into the framework (2), e.g., by including time $t$ as an additional (smooth) component of the noise $X$. This setting includes, for instance, fractional Brownian motion [CQ02] with Hurst parameter $H > 1/4$. It may help the reader to recall that, in the case when $X = B$, a multidimensional Brownian motion, all this amounts to enhance $B$ with Lévy’s stochastic area or, equivalently, with all iterated stochastic integrals of $B$ against itself, say $B_{s,t} = \int_s^t B_s \otimes dB$. The (rough-)pathwise solution concept then agrees with the usual notion of an SDE solution (in Itô- or Stratonovich sense, depending on which integration was used in defining $B$). As is well-known this provides a robust extension of the usual Itô framework of

stochastic differential equations with an exploding number of new applications (including non-linear SPDE theory, robustness of the filtering problem, non-Markovian Hörmander theory).

In a sense, the rough path interpretation of a differential equation is closely related to strong, pathwise error estimates of Euler- resp. Milstein-approximation to stochastic differential equations. For instance, Davie’s definition \cite{Dav07} of a (rough)pathwise SDE solution is

\begin{equation}
Y_t - Y_s = V_t(Y_s) B^s_t + V^k_t(Y_s) \partial_k V_j(Y_s) B^{s,j}_{s,t} + o(|t - s|) \quad \text{as } t \downarrow s,
\end{equation}

where we employ Einstein’s convention. In fact, this becomes an entirely \textit{deterministic} definition, only assuming

\[ \exists \alpha \in (1/3, 1/2) : |B_{s,t}| \leq C |t - s|^\alpha, |B_{s,t}| \leq C |t - s|^{2\alpha}, \]

something which is known to hold true almost surely (i.e. for \( C = C(\omega) < \infty \) a.s.), and something which is not at all restricted to Brownian motion. As the reader may suspect this approach leads to almost-sure convergence (with rates) of schemes which are based on the iteration of the approximation seen in the right-hand-side of (3). The practical trouble is that Lévy’s area, the antisymmetric part of \( B \), is notoriously difficult to simulate; leave alone the simulation of Lévy’s area for other Gaussian processes. It has been understood for a while, at least in the Brownian setting, that the truncated (or: simplified) Milstein scheme, in which Lévy’s area is omitted, i.e. replace \( B_{s,t} \) by \( \text{Sym}(B_{s,t}) \) in (3), still offers benefits: For instance, Talay \cite{Tal86} replaces Lévy area by suitable Bernoulli r.v. such as to obtain weak order 1 (see also Kloeden–Platen \cite{KP92} and the references therein). In the multilevel context, \cite{GS12} use this truncated Milstein scheme together with a sophisticated antithetic (variance reduction) method. Finally, in the rough path context this scheme was used in \cite{DNT12}: the convergence of the scheme can be traced down to an underlying Wong-Zakai type approximation for the driving random rough path – a (probabilistic!) result which is known to hold in great generality for stochastic processes, starting with \cite{CQ02} in the context of fractional Brownian motion, see \cite{FV10b} Ch. 15 and the references therein.

A rather difficult problem is to go from almost-sure convergence (with rates) to \( L^1 \) (or ever: \( L^r \) any \( r < \infty \)) convergence. Indeed, as pointed out in \cite{DNT12} Remark 1.2: "Note that the almost sure estimate [for the simplified Milstein scheme] cannot be turned into an \( L^1 \)-estimate [...]. This is a consequence of the use of the rough path method, which exhibits non-integrable (random) constants." The resolution of this problem forms the first contribution of this paper. It is based on some recent progress \cite{CLL,FR13}, initially developed to prove smoothness of laws for (non-Markovian) SDEs driven by Gaussian signals under a Hörmander condition, \cite{CF10,HP}.

Having established \( L^r \)-convergence (any \( r < \infty \), with rates) for implementable “simplified” Milstein schemes we move to our second contribution: a multilevel algorithm, in the sense of Giles \cite{Gil08b}, for stochastic differential equations driven by large classes of Gaussian signals. A \textit{strong}, \( L^2 \) error estimate ("rate \( \beta/2 \)") is the key assumption in Giles’ complexity theorem, and this is precisely what we have established in the first part. Some other extension of the Giles theorem are necessary; indeed it is crucial to allow for a weak rate of convergence \( \alpha < 1/2 \) (ruled out explicitly in \cite{Gil08b}) whenever we deal with driving signals with sample path regularity “worse” then Brownian motion. Luckily this can be done without too much trouble. Moreover, we more carefully keep track of the relevant constants in front of the asymptotic terms, a necessity in such an irregular regime.

More precisely, we consider the following scheme for approximating \( Y_t \), see \cite{DNT12, FV10b}. Given a equi-distant dissection \( D = (t_k) \) of \([0,T]\) with mesh \( h \), so that \( t_{k+1} - t_k \equiv h \) for all \( k \), write

\[ A \text{ well-known counter-example by Clark and Cameron \cite{CCS93} shows that it is impossible to get strong order 1 if only using Brownian increments.} \]
Let $X_{t_k,t_{k+1}}$ for the corresponding increments. We then define $Y_0 \equiv Y_0$ and
\begin{equation}
Y_{t_{k+1}} = Y_{t_k} + \sum_{i=1}^{3} \frac{1}{h} V_i \cdot V_i I(Y_{t_k}) X_{t_k,t_{k+1}} \cdots X_{t_k,t_{k+1}},
\end{equation}
where $I(y) = y$ is the identity function and the vector fields $V_1,\ldots,V_d$ are viewed as linear first order operators, acting on functions by $V_i g(y) = \nabla g(y) \cdot V_i(y)$. Whenever convenient we extend $Y$ to $[0,T]$ by linear interpolation. Moreover, the Einstein summation convention is in force. For a more detailed description of the algorithm we refer to Section 2.3. We are now able to state our main results; cf. Corollary [17].

**Theorem 1** (Strong rates). Let $X = (X^1,\ldots,X^d)$ be a continuous, zero-mean Gaussian process with independent components. Assume furthermore that each component has stationary increments and that
\[
\sigma^2(t-s) := E \left| X^i_t - X^i_s \right|^2
\]
where $\sigma^2$ is concave and $\sigma^2(\tau) = O(\tau^{1/\rho})$ as $\tau \to 0$ for some $\rho \in [1,2)$.

Let $Y$ be the solution to the rough differential equation (2) driven by (the rough path lift) of $X$ and $Y = Y^h$ be the approximate solution based on (4). Then we have strong convergence of (almost) rate $1/\rho - 1/2$. More precisely, for any $1 \leq r < \infty$ and $\delta > 0$, there exists a constant $C$ such that
\[
E \left( \sup_{t \in [0,T]} \left| Y_t - Y^h_t \right|^r \right)^{1/r} \leq C h^{1/\rho - 1/2 - \delta}.
\]

The reader should notice that the assumption on $X$ is met by multidimensional Brownian motion (with $\rho = 1$) in which case $Y$ is nothing but a Stratonovich solution of the SDE (1), which of course may be rewritten as Itô equation. More interestingly, $X$ may be a fractional Brownian motion (with $\rho = \frac{1}{2H} > 1$) in the interesting “rougner than Brownian” regime $H \in (1/4,1/2)$. Using Giles’ multi-level Monte Carlo methodology, we can greatly improve the complexity bounds for the discretization algorithm (4), see Theorem 22.

**Theorem 2** (Multilevel complexity estimate). Let $X$ and $Y$ be as in the previous theorem and $f : C([0,T],\mathbb{R}^m) \to \mathbb{R}^n$ a Lipschitz continuous functional. Then the Monte Carlo evaluation of a path-dependent functional of the form
\[
E(f(Y_t : 0 \leq t \leq T))
\]
to within a MSE of $\varepsilon^2$, can be achieved with computational complexity
\[
O\left(\frac{1}{\varepsilon^\theta}\right), \quad \forall \theta > \frac{2\rho}{2 - \rho}.
\]

As a sanity check, let us compare this results with the corresponding, well-known results for classical stochastic differential equations (here: in Stratonovich sense) driven by $d$-dimensional Brownian motion $B$. The assumptions on $X$ are clearly met with $\rho = 1$. As a consequence, we obtain strong convergence of (almost) rate $1/2$ in agreement with the well-known strong rate $1/2$ in the classical setting. Concerning our multilevel complexity estimate, we obtain (almost) order $\varepsilon^{-2}$ which is arbitrarily “close” to known result $O\left(\varepsilon^{-2} (\log \varepsilon)^2\right)$ [G10Sa, G10Sb], recently sharpened to $O\left(\varepsilon^{-2}\right)$ [GS12] with the aid of a suitable antithetic multilevel correction estimator.

Let us summarize the (computational) benefits of the multilevel approach in the present (“rougher than Brownian”) setting. A direct Monte Carlo implementation of the scheme (4) would require a
Definitions of the basic objects and all relevant notation may be found in the appendix. A more detailed account to the theory of rough paths may be found in the monographs [LQ02], [LCL07] or [FV10b].

1. Rough path estimates revisited

In this section, we revisit and improve some classical estimates used in rough paths theory. Definitions of the basic objects and all relevant notation may be found in the appendix. A more detailed account to the theory of rough paths may be found in the monographs [LQ02], [LCL07] or [FV10b].

1.1. Improved bounds for the Lipschitz constant of the Itô-Lyons map. It is well-known that the Lipschitz constant of the Itô-Lyons solution map for an RDE driven by a rough path \( x \) is of the order \( O(\exp(C\|x\|_{p-\text{var}}^p)) \). Considering Gaussian driving signals, this (random) constant fails to have finite \( q \)-th moments for any \( q \). In this section, we improve the deterministic estimates for the Lipschitz constant slightly which will allow us to derive the desired estimates.

Recall the following definition, taken from [CLL]:

**Definition 3.** Let \( \omega \) be a control function. For \( \alpha > 0 \) and \( [s, t] \subset [0, T] \) we set
\[
\tau_0(\alpha) = s
\]
\[
\tau_{i+1}(\alpha) = \inf \{ u : \omega(\tau_i, u) \geq \alpha, \tau_i(\alpha) < u \leq t \} \wedge t
\]
and define
\[
N_{\alpha,[s,t]}(\omega) = \sup \{ n \in \mathbb{N} \cup \{0\} : \tau_n(\alpha) < t \}.
\]
When \( \omega \) arises from the (homogeneous) \( p \)-variation norm \( \| \cdot \|_{p-\text{var}} \) of a \((p\text{-rough})\) path, \( x \), i.e., \( \omega_x = \|x\|_{p-\text{var},[\cdot,\cdot]}^p \), we shall also write \( N_{\alpha,[s,t]}(x) := N_{\alpha,[s,t]}(\omega_x) \).

It is easy to see that \( N_{\alpha,[0,T]}(x) \lesssim \|x\|_{p-\text{var},[0,T]}^p \) but the tail estimates for \( N_{\alpha,[0,T]}(X) \) are significantly better than for \( \|X\|_{p-\text{var},[0,T]}^p \) when we consider Gaussian lifts \( X \), cf. [CLL] and [PR13].

Next, we give the main result from this section.

**Theorem 4.** Consider the RDEs
\[
dy^i = V^i(y^i) \, dx^i; \quad y^i_0 \in \mathbb{R}^\ell
\]
for \( i = 1, 2 \) on \( [0, T] \) where \( V^1 \) and \( V^2 \) are two families of vector fields, \( \gamma > p \) and \( \nu \) is a bound on \( |V^1|_{\text{Lip}^{\gamma}} \) and \( |V^2|_{\text{Lip}^{\gamma}} \). Then for every \( \alpha > 0 \) there is a constant \( C = C(\gamma, p, \nu, \alpha) \) such that
\[
\|y^1 - y^2\|_{\infty,[0,T]} \leq C \left( \|y_0^1 - y_0^2\| + |V^1 - V^2|_{\text{Lip}^{\gamma-1}} + \rho_{p-\text{var},[0,T]}(x^1, x^2) \right) \\
\times \exp \left\{ C \left( N_{\alpha,[0,T]}(x^1) + N_{\alpha,[0,T]}(x^2) + 1 \right) \right\}
\]
holds.

\(^2\)By lack of the Markov property, the standard techniques of deriving weak error estimates fail in the setting of an RDE driven by a general Gaussian process such as a fBM. Thus, computing the weak rate of convergence for the simplified Euler scheme would be a non-trivial task. On the other hand, we present a numerical example in Section 4 where the weak order is equal to the strong order even in a standard Brownian motion setting.
Remark 5. Comparing the result of Theorem 4 with [FV10b, Theorem 10.26], one sees that we obtain a slightly weaker result; namely, the distance between \( y^1 \) and \( y^2 \) is measured here in uniform topology instead of \( p \)-variation topology. However, with little more effort, one can show that the same estimate holds for \( \rho_{p\text{-var};[0,T]} (y^1, y^2) \) instead of \( \|y^1 - y^2\|_{\infty;[0,T]} \).

The proof of Theorem 4 will be given at the end of this section. We first prove some preparational Lemmata.

Recall that if \( \omega^1 \) and \( \omega^2 \) are controls, also \( \omega^1 + \omega^2 \) is a control.

Lemma 6. Let \( \omega^1 \) and \( \omega^2 \) be two controls. Then

\[
N_{\alpha,[s,t]}(\omega^1 + \omega^2) \leq 2N_{\alpha,[s,t]}(\omega^1) + 2N_{\alpha,[s,t]}(\omega^2) + 2
\]

for every \( s < t \) and \( \alpha > 0 \).

Proof. If \( \omega \) is any control, set

\[
\omega_{\alpha}(s,t) := \sup_{(t_i)_{i=0}^{N_{\alpha,[s,t]}(\omega)} \leq \alpha} \sum_{i} \omega(t_i, t_{i+1}).
\]

If \( \bar{\omega} := \omega^1 + \omega^2 \), \( \bar{\omega}(t_i, t_{i+1}) \leq \alpha \) implies \( \omega^i(t_i, t_{i+1}) \leq \alpha \) for \( i = 1,2 \) and therefore \( \bar{\omega}_{\alpha}(s,t) \leq \omega^1_{\alpha}(s,t) + \omega^2_{\alpha}(s,t) \). From Proposition 4.6 in [CLL] we know that \( \omega^i_{\alpha}(s,t) \leq \alpha (2N_{\alpha,[s,t]}(\omega^i) + 1) \) for \( i = 1,2 \). (Strictly speaking, Proposition 4.6 is formulated for a particular control \( \omega \), namely the control induced by the \( p \)-variation of a rough path. However, the proof only uses general properties of control functions and the conclusion remains valid.) We conclude

\[
\alpha N_{\alpha,[s,t]}(\bar{\omega}) = \sum_{i=0}^{N_{\alpha,[s,t]}(\bar{\omega})-1} \bar{\omega}(\tau_i(\alpha), \tau_{i+1}(\alpha)) \leq \bar{\omega}_\alpha(s,t) \leq \omega^1_\alpha(s,t) + \omega^2_\alpha(s,t) \leq \alpha (2N_{\alpha,[s,t]}(\omega^1) + 2N_{\alpha,[s,t]}(\omega^2) + 2).
\]

\[\square\]

Lemma 7. Let \( \omega^1 \) and \( \omega^2 \) be two controls and assume that \( \omega^2(s,t) \leq K \). Then

\[
N_{\alpha,[s,t]}(\omega^1 + \omega^2) \leq N_{\alpha-K,[s,t]}(\omega^1)
\]

for every \( \alpha > K \).

Proof. Set \( \bar{\omega} := \omega^1 + \omega^2 \) and

\[
\bar{\tau}_0(\alpha) = s \quad \text{and} \quad \bar{\tau}_{i+1}(\alpha) = \inf \{ u : \bar{\omega} (\bar{\tau}_i, u) \geq \alpha, \bar{\tau}_i(\alpha) < u \leq t \} \land t.
\]

Similarly, we define \( (\tau_i)_{i \in \mathbb{N}} = (\tau_i(\alpha - K))_{i \in \mathbb{N}} \) for \( \omega^1 \). It suffices to show that \( \bar{\tau}_i \geq \tau_i \) for \( i = 0, \ldots, N_{\alpha,[s,t]}(\bar{\omega}) \). We do this by induction. For \( i = 0 \), this is clear. If \( \bar{\tau}_i \geq \tau_i \) for some \( i \leq N_{\alpha,[s,t]}(\bar{\omega}) - 1 \), superadditivity of control functions gives

\[
\alpha = \bar{\omega}(\bar{\tau}_i, \bar{\tau}_{i+1}) \leq \omega^1(\tau_i, \bar{\tau}_{i+1}) + K
\]

which implies \( \tau_{i+1} \leq \bar{\tau}_{i+1} \). \[\square\]
Lemma 8. Let \( s < t \in [0,T] \) and assume that \( \|x^i\|_{\omega;[s,t]} \leq 1 \) for \( i = 1, 2 \). Then there is a constant \( C = C(\gamma, p) \) such that
\[
\nu|y^1 - y^2|_{\infty;[s,t]} \leq \left[ \nu|y_1^1 - y_2^1| + |V^1 - V^2|_{\text{Lip}^\gamma - 1} + \nu \rho_{p - \omega;[s,t]}(x^1, x^2) \right] \times (N_{\alpha;[s,t]}(\omega) + 1) \exp \left\{ C \nu \alpha(N_{\alpha;[s,t]}(\omega) + 1) \right\}
\]
for every \( \alpha > 0 \).

Proof. Set \( \bar{y} = y^1 - y^2 \) and
\[
\kappa = \frac{|V^1 - V^2|_{\text{Lip}^\gamma - 1}}{\nu} + \rho_{p - \omega;[s,t]}(x^1, x^2).
\]
From [FV10] Theorem 10.26 we can deduce that there is a constant \( C = C(\gamma, p) \) such that
\[
|\bar{y}_{u,v}| \leq C \nu \omega(u, v)^{1/p} \|\bar{y}_u\| + \kappa \exp \left\{ C \nu \omega(u, v) \right\}
\]
for every \( u < v \in [s, t] \). From \( |\bar{y}_{u,v}| \geq |\bar{y}_{s,v}| - |\bar{y}_{s,u}| \) we obtain
\[
|\bar{y}_{s,v}| \leq C \nu \omega(u, v)^{1/p} \|\bar{y}_u\| + \kappa \exp \left\{ C \nu \omega(u, v) \right\} \leq \left\{ |\bar{y}_s| + |\bar{y}_{s,s}| + \kappa \exp \left\{ C \nu \omega(u, v) \right\} \right\}
\]
for \( s \leq u < v \leq t \). Now let \( s = \tau_0 < \tau_1 < \ldots < \tau_M < \tau_{M+1} = v \leq t \) for \( M \geq 0 \). By induction, one sees that
\[
|\bar{y}_{s,v}| \leq (M + 1)|\bar{y}_s| + \kappa \exp \left\{ C \nu \sum_{i=0}^{M} \omega(\tau_i, \tau_{i+1}) \right\} \leq C^{M+1} |\bar{y}_s| + \kappa \exp \left\{ C \nu \sum_{i=0}^{M} \omega(\tau_i, \tau_{i+1}) \right\}.
\]
It follows that for every \( v \in [s, t] \),
\[
|\bar{y}_{s,v}| \leq (|\bar{y}_s| + \kappa) (N_{\alpha;[s,t]}(\omega) + 1) \exp \left\{ C \nu \alpha(N_{\alpha;[s,t]}(\omega) + 1) \right\},
\]
therefore
\[
|\bar{y}_{v}| \leq (|\bar{y}_s| + \kappa) (N_{\alpha;[s,t]}(\omega) + 1) \exp \left\{ C \nu \alpha(N_{\alpha;[s,t]}(\omega) + 1) \right\} + |\bar{y}_s|
\]
and finally
\[
|\bar{y}_{\infty;[s,t]}| \leq (|\bar{y}_s| + \kappa) (N_{\alpha;[s,t]}(\omega) + 1) \exp \left\{ C \nu \alpha(N_{\alpha;[s,t]}(\omega) + 1) \right\}.
\]
\(\square\)

Proof of Theorem 3. Let \( \omega \) be a control such that \( \|x^i\|_{p - \omega;[0,T]} \leq 1 \) for \( i = 1, 2 \) (the precise choice of \( \omega \) will be made later). From Lemma 8 we know that there is a constant \( C = C(\gamma, p, \nu, \alpha) \) such that
\[
|y^1 - y^2|_{\infty;[0,T]} \leq \left[ |y_0^1 - y_0^2| + |V^1 - V^2|_{\text{Lip}^\gamma - 1} + \rho_{p - \omega;[s,t]}(x^1, x^2) \right] \times \exp \left\{ C(N_{\alpha;[s,t]}(\omega) + 1) \right\}.
\]
Now we set \( \omega = \omega_{x^1, x^2} \) where
\[
\omega_{x^1, x^2}(s, t) = \|x^1\|_{p - \omega;[s,t]} + \|x^2\|_{p - \omega;[s,t]} + \sum_{k=1}^{[p]} \left( \frac{\rho_{p - \omega;[s,t]}(x^1, x^2)}{\rho_{p - \omega;[0,T]}(x^1, x^2)} \right)^{p/k}.
\]
It is easy to check that
\[
\|x^1\|_{p-\omega_{\frac{1}{2},\frac{1}{2}};[0,T]} \leq 1,
\]
\[
\|x^2\|_{p-\omega_{\frac{1}{2},\frac{1}{2}};[0,T]} \leq 1 \quad \text{and}
\]
\[
\rho_{p-\omega_{\frac{1}{2},\frac{1}{2}};[0,T]}(x^1, x^2) \leq \rho_{p-\text{var};[0,T]}(x^1, x^2).
\]
Finally, if \( \alpha > [p] \) we can use Lemma 7 and Lemma 8 to see that
\[
N_{\alpha, [0,T]}(\omega_{\frac{1}{2},\frac{1}{2}}^1, \omega_{\frac{1}{2},\frac{1}{2}}^2) + 1 \leq N_{\alpha- [p], [0,T]}(\omega_{\frac{1}{2},\frac{1}{2}}^1 + \omega_{\frac{1}{2},\frac{1}{2}}^2) + 1
\]
\[
\leq 3 \left( N_{\alpha- [p], [0,T]}(x^1) + N_{\alpha- [p], [0,T]}(x^2) + 1 \right).
\]
Substituting \( \alpha \to \alpha + [p] \) gives the claimed estimate. \( \square \)

1.2. Improved bounds for Euler approximations based on entire rough path. We are now interested in proving a similar estimate for the distance between Euler-/Milstein approximations for rough paths and the actual solution (for the purpose of unified terminology, in the sequel we will only speak of Euler-schemes). Recall the notation from \[ \[FV10b\]: If \( V = (V_1, \ldots, V_d) \) is a collection of sufficiently smooth vector fields on \( \mathbb{R}^r \), \( g \in TN(\mathbb{R}^d) \) and \( y \in \mathbb{R}^r \), we define an increment of the step-\( N \) Euler scheme by
\[
\mathcal{E}_{(V)}(y, g) := \sum_{k=1}^N V_{i_1} \cdots V_{i_k} I(y) g^{k, i_1, \ldots, i_k}
\]
where \( g^{k, i_1, \ldots, i_k} = \pi_k(g)^{i_1, \ldots, i_k} \in \mathbb{R} \), \( I \) is the identity on \( \mathbb{R}^r \) and every \( V_j \) is identified with the first-order differential operator \( V_j(y) \frac{\partial}{\partial y_j} \) (throughout, we use the Einstein summation convention). Furthermore, we set
\[
\mathcal{E}^g y := y + \mathcal{E}_{(V)}(y, g).
\]
Given \( D = \{ 0 = t_0 < \ldots < t_n = T \} \) and a path \( x \in \mathcal{C}_{0}^{p-\text{var}}([0, T]; G^{[p]}) \) we define the (step-\( N \)) Euler approximation to the RDE solution \( y \) of
\[
dy = V(y) \; dx
\]
with starting point \( y_0 \in \mathbb{R}^r \) at time \( t_k \in D \) by
\[
y^{\text{Euler};D}_{t_k} := \mathcal{E}^{e_{t_k-t_0} y_0} \circ \cdots \circ \mathcal{E}^{e_{t_{n-1}-t_0} y_{t_{n-1}}} y_0.
\]

**Theorem 9.** Let \( x \in \mathcal{C}_{0}^{p-\text{var}}([0, T]; G^{[p]}) \) and set \( \omega(s, t) = \|x\|_{p-\text{var};[s, t]} \). Assume that \( V \in \text{Lip}^\theta \) for some \( \theta > p \) and let \( \nu \geq |V|_{\text{Lip}^\theta} \). Choose \( N \in \mathbb{N} \) such that \( \lfloor p \rfloor \leq N \leq \theta \). Fix a dissection \( D = \{ 0 = t_0 < \ldots < t_n = T \} \) of \( [0, T] \) and let \( y_T^{\text{Euler};D} \) denote the step-\( N \) Euler approximation of \( y \). Then for every \( \zeta \in \left[ \frac{N}{p}, \frac{N+1}{p} \right] \) and \( \alpha > 0 \) there is a constant \( C = C(p, \theta, \zeta, N, \nu, \alpha) \) such that
\[
\left| y_T - y_T^{\text{Euler};D} \right| \leq C \exp \left\{ C \left( N_{\alpha, [0,T]}(x) + 1 \right) \right\} \sum_{k=1}^n \omega(t_{k-1}, t_k)^{\zeta}.
\]
In particular, if \( x \) is a H"older rough path and \( |t_{k+1} - t_k| \leq |D| \) for all \( k \) we obtain
\[
\left| y_T - y_T^{\text{Euler};D} \right| \leq C T \left\| x \right\|_{1/p-\text{H"older};[0,T]}^{\zeta} \exp \left\{ C \left( N_{\alpha, [0,T]}(x) + 1 \right) \right\} |D|^{\zeta-1}
\]
Proof. We basically repeat the proof of [FV10b, Theorem 10.30]. Recall the notation \( \pi_{(V)} (s, y_s; x) \) for the (unique) solution of (5) with starting point \( y_s \) at time \( s \). Set
\[
z^k = \pi_{(V)} (t_k, e^{t_s-t_0} y_0; x).
\]
Then \( z^0 = y_t, z^k = e^{t_s-t_0} y_0 \) for every \( k = 1, \ldots, n \) and \( z^n_T = y_T^{\text{Euler}; D} \), hence
\[
|y_T - y_T^{\text{Euler}; D}| \leq \sum_{k=1}^n |z^k_T - z^{k-1}_T|.
\]
One can easily see that
\[
z^{k-1}_T = \pi_{(V)} (t_{k-1}, z^{k-1}_{t_{k-1}}; x) = \pi_{(V)} (t_k, z^{k-1}_T; x)
\]
for all \( k = 1, \ldots, n \). Applying Theorem 4 (in particular the Lipschitzness in the starting point) we obtain for any \( \alpha > 0 \)
\[
|z^k_T - z^{k-1}_T| \leq c_1 |z^k_T - z^{k-1}_T| \exp \{c_1 (N, [0,T](x) + 1)\}
\]
Moreover (cf. [FV10b, Theorem 10.30]),
\[
|z^k_{t_k} - z^{k-1}_{t_k}| \leq \left| \pi_{(V)} (t_{k-1}, \cdot; x)_{t_k-1,t_k} - E_{(V)} (\cdot, S_N (x))_{t_k-1,t_k} \right|.
\]
Let \( \delta \in [0,1) \) such that \( \zeta = \frac{N+\delta}{p} \). Since \( (N + \delta) - 1 < N \leq \gamma \) we have \( V \in \text{Lip}^{(N+\delta)-1} \). Thus we can apply [FV10b, Corollary 10.15] to see that
\[
\left| \pi_{(V)} (t_{k-1}, \cdot; x)_{t_k-1,t_k} - E_{(V)} (\cdot, S_N (x))_{t_k-1,t_k} \right|_\infty \leq c_2 \left( |V|_\text{Lip}^{(N+\delta)-1} \|x\|_{\text{p-var};[t_{k-1},t_k]} \right)^{N+\delta}
\]
which gives the claim. \( \square \)

2. Probabilistic convergence results for RDEs

Recall that our basic object is a multidimensional, zero-mean Gaussian process \( X = (X^1, \ldots, X^d) \) with independent components and continuous sample paths. The covariance function will be denoted by \( R_X \). The existence of a lift \( \tilde{X} \) of \( X \) to a process with sample paths in a rough paths space follows if \( R_X \) is smooth enough in terms of 2-dimensional \( \rho \)-variation; more precisely, if \( V_{\rho}(R_X; [0,T]^2) < \infty \) for some \( \rho < 2 \), \( \tilde{X} \) exists in a natural way (cf. [FV10a] or Theorem 25 in the appendix). The associated Cameron-Martin space of \( X \) will be denoted by \( \mathcal{H} \). Recall that every path \( \phi \in \mathcal{H} \) has the form \( \phi_t = E(X_t Z) \) where \( Z \) is a random variable lying in the \( L^2 \)-closure of span \( \{X_t : t \in [0,T]\} \) and \( \langle \phi, \tilde{\phi} \rangle_{\mathcal{H}} = E(Z \bar{Z}) \) if \( \phi_t = E(Z X_t), \tilde{\phi}_t = E(\bar{Z} X_t) \). In the following, smoothness of the Cameron-Martin paths in terms of its \( \rho \)-variation index will be crucial. More precisely, we will say that complementaary Young-regularity holds for the trajectories of \( X \) and the paths in the Cameron-Martin space if the trajectories have finite \( \rho \)-variation almost surely and if there is a continuous embedding
\[
\nu: \mathcal{H} \to C^{q-\text{var}} \quad \text{for some } q \leq p \text{ such that } \frac{1}{p} + \frac{1}{q} > 1.
\]
Complementaary Young-regularity will be a fundamental assumption. We recall some sufficient conditions:
(1) If $R_X$ has finite $\rho$-variation, the Cameron-Martin paths have finite $\rho$-variation and complementary Young-regularity holds for $\rho \in [1, 3/2)$. In this case,

$$\|\iota\|_{\mathcal{H} \rightarrow C^{q-\text{var}}} \leq \sqrt{V_{\rho}(R_X; [0, T]^2)}$$

(cf. [FV10a, Proposition 17]).

(2) If $R_X$ has finite mixed $(1, \rho)$-variation, the Cameron-Martin paths have finite $q$-variation for

$$q = \frac{1}{2\rho} + \frac{1}{2}$$

and complementary Young-regularity holds for $\rho \in [1, 2)$. In this case,

$$\|\iota\|_{\mathcal{H} \rightarrow C^{q-\text{var}}} \leq \sqrt{V_{1, \rho}(R_X; [0, T]^2)}$$

(cf. [FGR13, Theorem 1]).

(3) If $X$ has stationary increments and $\sigma^2(u) := E(|X_u - X_0|^2)$ is concave with $\sigma^2(u) \leq C\sigma|u|^{1+\rho}$, there is a constant $l > 0$ such that $R_X$ has finite mixed $(1, \rho)$-variation on squares $[s, t]^2$ with $|t - s| \leq l$ and

$$V_{1, \rho}(R_X; [s, t]^2) \leq 5C\sigma|t - s|^{1+\rho}$$

holds for all $|t - s| \leq l$ (cf. [FGR13, Theorem 6]). Hence we have complementary Young-regularity for $\rho \in [1, 2)$ and $\|\iota\|_{\mathcal{H} \rightarrow C^{q-\text{var}}} \leq C_{K, l, \rho, T}$ with $K \geq C\sigma$. This covers fractional Brownian motion with Hurst parameter $H \in (1/4, 1/2]$.

In the following subsection, we will establish $L^p$-convergence rates for step-$N$ Euler approximations based on the entire Gaussian rough paths, i.e. schemes involving iterated (random) integrals up to order $N$. Although these schemes are hard to implement (the distributions of the iterated integrals are in general not known) it will serve as a stepping stone to more simple schemes. We continue by giving $L^p$-rates for the Wong-Zakai theorem in the Gaussian case. Putting together both results, we can give $L^p$ convergence rates for an (easy-to-implement) simplified Euler scheme presented first in [DNT12]. We will see that the (sharp) almost sure convergence rates obtained in [FR] also hold in $L^p$.

2.1. $L^r$-rates for step-$N$ Euler approximation (based on entire rough path). For simplicity, the following Theorem is formulated only in the Hölder case.

**Theorem 10.** Assume that $V_{\rho}(R_X; [s, t]^2) \leq K|t - s|^{1/\rho}$ holds for all $s < t$, some $\rho \in [1, 2)$ and a constant $K$. Assume that

$$\iota: \mathcal{H} \rightarrow C^{q-\text{var}}$$

for some $q < 2$, let $M \geq \|\iota\|_{\mathcal{H} \rightarrow C^{q-\text{var}}}$ and assume that complementary Young-regularity holds.

Choose $p > 2\rho$, assume that $V \in \text{Lip}^\theta$ for some $\theta > p$ and let $\nu \geq |V|_{\text{Lip}^\theta}$. Set

$$D = \{0 < h < 2h < \ldots < (\lfloor T/h \rfloor - 1)h < T\}$$

and let $Y_{T}^{\text{Euler}; D}$ denote the step-$N$ Euler approximation of $Y$, the (pathwise) solution of

$$dY = V(Y) \, dX; \quad Y_0 \in \mathbb{R}^e$$

where $N$ is chosen such that $|p| \leq N \leq \theta$. 

Then for every \( r \geq 1, r' > r \) and \( \zeta \in \left[ \frac{N}{p}, \frac{N+1}{p} \right] \) there is a constant \( C = C(\rho, p, q, \theta, \nu, K, M, r, r', N, \zeta) \) such that
\[
\|Y_T - Y_T^{Euler,D}\|_{L^r} \leq CT \left\| X^{\rho, p-Hol;[0,T]} \right\|_{L^{r'}} h^{\zeta - 1}
\]
holds for all \( h > 0 \).

**Remark 11.** By choosing \( \hat{p} \in (2\rho, p) \) one has \( \frac{N+1}{p} > \frac{N+1}{\hat{p}} \) and applying the Theorem with \( \hat{p} \) instead of \( p \) shows that
\[
\|Y_T - Y_T^{Euler,D}\|_{L^r} \lesssim h^{\frac{N+1}{\hat{p}} - 1}
\]
holds for every \( p > 2\rho \) if \( h \to 0 \).

**Proof of Theorem** [1] Lemma 5 together with Corollary 2 and Remark 1 in [FR13] show that there is a \( \alpha = \alpha(p, \rho, K) > 0 \) and a positive constant \( c_1 = c_1(p, q, \rho, K) \) such that we have the tail estimate
\[
P(N_{\alpha, [0,T]}(X) > u) \leq \exp \left\{ -c_1 \alpha^2 u^{2/q} \right\}
\]
for all \( u > 0 \). Now we use the pathwise estimate [6] and take the \( L^r \) norm on both sides. The Hölder inequality shows that
\[
\|Y_T - Y_T^{Euler,D}\|_{L^r} \leq c_1 T \left\| X^{\rho, p-Hol;[0,T]} \right\|_{L^{r'}} \exp \left\{ C (N_{\alpha, [0,T]}(X) + 1) \right\} \left\| D \right\|^{\zeta - 1}
\]
holds for some (possibly large) \( r'' > r \). Our tail estimate for \( N_{\alpha, [0,T]}(X) \) shows that the right hand side is finite which gives the claim. \( \square \)

### 2.2. \( L^r \)-rates for Wong-Zakai approximations.

We aim to formulate a version of the Wong-Zakai Theorem which contains convergence rates in \( L^r \), any \( r \geq 1 \) for a class of suitable approximations \( X^h \) of \( X \). By this, we mean that

1. \((X^h, X): [0, T] \to \mathbb{R}^{d+\hat{d}}\) is jointly Gaussian, \((X^{h,i}, X^i)\) and \((X^{h,j}, X^j)\) are independent for \( i \neq j \) and
2. \( \sup_{h \in [0, 1]} V_{\rho} \left( R_{(X^h, X^i)}; [0, T] \right)^2 =: K < \infty \)
3. Uniform convergence of the second moments:
4. \( \sup_{t \in [0, T]} E \left[ \left| X^h_t - X_t \right|^2 \right] =: \delta(h)^{1/\rho} \to 0 \) for \( h \to 0 \).

**Example 12.** A typical example of such approximations are the piecewise linear approximations of \( X(\omega) \) at the time points \( \{0 < h < 2h < \cdots < ([T/h] - 1)h < T\} \) (see [FY10b, Chapter 15.5]). In the case \( V_{\rho} \left( R_X; [s, t] \right)^2 \lesssim \left| t - s \right|^{1/\rho} \) (i.e. if we deal with Hölder rough paths), one can show that \( \delta(h) \lesssim h \).

**Theorem 13.** Let \( X: [0, T] \to \mathbb{R}^d \) be a centered Gaussian process with continuous sample paths, independent components and covariance of finite \( \rho \)-variation for some \( \rho \in [1, 2] \). Let \((X^h)_{h>0}\) be a family of suitable approximations as seen in the beginning of this section. Let \( H^h \) and \( H^0 \) denote the Cameron-Martin spaces of the processes \( X^h \) resp. \( X \). Assume that
\[
i^h: H^h \to C_q^{\text{var}}
\]
for some \( q < 2 \), let \( M \geq \|\delta^h\|_{H \to C_q^{\text{var}}} \) for all \( h > 0 \) and assume that complementary Young-regularity holds. Let \( X \) and \( X^h \) denote the lift of \( X \) resp. \( X^h \) to a process with \( \rho \)-rough sample paths.
for some $p > 2\rho$. Let $V = (V_1, \ldots, V_d)$ be a collection of vector fields in $\mathbb{R}^c$. Choose $\eta < \frac{1}{\rho} - \frac{2}{3}$ and assume that $|V|_{\mathit{Lip}^\theta} \leq \nu < \infty$ for some $\theta > \frac{2\rho}{1 - 2\rho\eta}$. Let $Y, Y^h : [0, T] \to \mathbb{R}^c$ denote the pathwise solutions to the equations

\[
\begin{align*}
  dY_t & = V(Y_t) dX_t; \quad Y_0 \in \mathbb{R}^c \\
  dY^h_t & = V(Y^h_t) dX^h_t; \quad Y^h_0 = Y_0 \in \mathbb{R}^c.
\end{align*}
\]

Then, for any $r \geq 1$ there is a constant $C = C(\rho, p, q, \theta, \nu, K, M, \eta, r)$ such that

\[
\left| \left| Y^h - Y \right|_{\infty;[0,T]} \right|_{L^r} \leq C\delta(h)^\eta
\]

holds for all $h > 0$.

**Remark 14.** We give some sufficient conditions under which the assumptions on the Cameron-Martin paths in Theorem [13] are fulfilled:

1. If the Cameron-Martin paths associated to the process $X$ have finite $q$-variation, if complementary Young-regularity holds for the trajectories of $X$ and the Cameron-Martin paths and if the operators $\Lambda_h : \omega \to \omega^h$ are uniformly bounded in the sense that

\[
\sup_{h > 0} \left\| \Lambda_h \right\|_{C^{q-\text{var}} \to C^{q-\text{var}}} < \infty,
\]

we have $\sup_{h > 0} \| \omega^h \|_{H \to C^{q-\text{var}}} < \infty$. This is the case, for instance, when dealing with piecewise-linear or mollifier approximations.

2. In the case $\rho \in [1, 3/2)$, the assumptions are always fulfilled using [7] and the Cameron-Martin embedding from [FV10a, Proposition 17] and we can set $M = \sqrt{K}$.

3. For $\rho \in [1, 2)$, another sufficient condition is uniform mixed $(1, \rho)$-variation:

\[
\sup_{h \in (0,1]} V_{1, \rho}(R(X^h, X); [0, T]) =: K' < \infty.
\]

In this case, we can choose $K = K'$ and $M = \sqrt{K'}$ (see [FGR13, Theorem 1]). This holds, for instance, for fractional Brownian motion with Hurst parameter $H > 1/4$.

**Proof of Theorem [13]** By assumption, we know that

\[
|\phi|_{q-\text{var}} \leq M |\phi|_{H^h}
\]

holds for every $\phi \in \mathcal{H}^h$ and $h \geq 0$. As in the proof of Theorem [10] we can find a $\alpha = \alpha(p, \rho, K) > 0$ and a positive constant $c_1 = c_1(p, q, \rho, M)$ such that we have the uniform tail estimate

\[
P(N_{\alpha, [0,T]}(X^h) > u) \leq \exp \left\{ -c_1 \alpha^{2/p} u^{2/q} \right\}
\]

for all $u > 0$ and $h \geq 0$. Choose $\hat{p} \in \left( \frac{2p}{1 - 2\rho\eta}, \theta \right)$ and set $\tilde{X}^h = S_{[\hat{p}]}(X^h)$ and $\tilde{X} = S_{[\hat{p}]}(X)$.

Lipschitzness of the map $S_{[\hat{p}]}$ and [FRI13, Lemma 2] show that also

\[
P(N_{\alpha, [0,T]}(\tilde{X}^h) > u) \leq \exp \left\{ -c_1 \alpha^{2/p} u^{2/q} \right\}
\]

hold for all $u > 0$ and $h \geq 0$ for a possibly smaller $\alpha > 0$. Now we use Corollary [4] and the Cauchy-Schwarz inequality to see that

\[
\left| \left| Y^h - Y \right|_{\infty;[0,T]} \right|_{L^r} \leq c_2 \left| P_{\hat{p}-\text{var};[0,T]}(\tilde{X}^h, \tilde{X}) \right|_{L^2} \left( \exp \left\{ c_2 \left( N_{\alpha, [0,T]}(\tilde{X}^h) + N_{\alpha, [0,T]}(\tilde{X}) + 1 \right) \right\} \right)_{L^2}
\]

for some $c_2 > 0$. Let $\theta > \frac{2\rho}{1 - 2\rho\eta}$ and assume that $|V|_{\mathit{Lip}^\theta} \leq \nu < \infty$ for some $\theta > \frac{2\rho}{1 - 2\rho\eta}$. Let $Y, Y^h : [0, T] \to \mathbb{R}^c$ denote the pathwise solutions to the equations

\[
\begin{align*}
  dY_t & = V(Y_t) dX_t; \quad Y_0 \in \mathbb{R}^c \\
  dY^h_t & = V(Y^h_t) dX^h_t; \quad Y^h_0 = Y_0 \in \mathbb{R}^c.
\end{align*}
\]
for a constant $c_2$. The uniform tail estimates \([8]\) show that
\[
\sup_{h \geq 0} \left| \exp \left\{ c_2 \left( N_{\alpha,[0,T]}(\tilde{X}^h) + N_{\alpha,[0,T]}(\tilde{X}) + 1 \right) \right\} \right|_{L^{2r}} \leq c_3 < \infty.
\]
Using \([FR, Theorem 6]\) gives
\[
\left| \rho_{\varphi,-\var}^{\varphi}([0,T]) (\tilde{X}^h, \tilde{X}) \right|_{L^{2r}} \leq c_4 \sup_{t \in [0,T]} |X_t^h - X_t|^{1 - \frac{4}{\varphi}}_t \delta (h)^\eta
\]
for a constant $c_4$ which finishes the proof. \(\square\)

2.3. \(L'\)-rates for the simplified Euler schemes. For \(N \geq 2\), step-\(N\) Euler schemes contain iterated integrals whose distributions are not easy to simulate when dealing with Gaussian processes. In contrast, the simplified step-\(N\) Euler schemes avoid this difficulty by substituting the iterated integrals by a product of increments. In the context of fractional Brownian motion, it was introduced in \([DNT12]\). We make the following definition: If \(V = (V_1, \ldots, V_d)\) is sufficiently smooth, \(x\) is a \(p\)-rough path, \(y \in \mathbb{R}^\epsilon\) and \(N \geq |p|\), we set
\[
\mathcal{E}_{\text{simple}} (y, S_N (x))_{s,t} := \sum_{k=1}^{N} \frac{1}{h_k^\alpha} V_i \cdots V_k I (y) x_{s,t}^k
\]
for \(s < t\) and
\[
\mathcal{E}_{\text{simple}} S_N (x)_{s,t} := y + \mathcal{E}_{\text{simple}} \left( y, S_N (x)_{s,t} \right).
\]
Given \(D = \{0 = t_0 < \ldots < t_n = T\}\) and a path \(x \in C_0^{\eta,\varphi}(0,T;G^{[p]}(\mathbb{R}^d))\) we define the simplified (step-\(N\)) Euler approximation to the RDE solution \(y\) of
\[
dy = V (y) \, dx
\]
with starting point \(y_0 \in \mathbb{R}^\epsilon\) at time \(t_k \in D\) by
\[
y_{t_k}^{\text{simple Euler};D} := \mathcal{E}_{\text{simple}}^{t_{k-1},t_k} y_0 := \mathcal{E}_{\text{simple}}^{S_N(x),t_{k-1},t_k} \circ \cdots \circ \mathcal{E}_{\text{simple}}^{S_N(x),0,t_1} y_0
\]
and at time \(t \in (t_k, t_{k+1})\) by
\[
y_{t}^{\text{simple Euler};D} := \left( \frac{t - t_k}{t_{k+1} - t_k} \right) \left( y_{t_{k+1}}^{\text{simple Euler};D - y_{t_k}^{\text{simple Euler};D}} + y_{t_k}^{\text{simple Euler};D} \right).
\]

**Theorem 15.** Let \(X : [0,T] \to \mathbb{R}^d\) be as in Theorem 10 with covariance of finite \(\rho\)-variation, \(\rho < 2\). Choose \(N \geq \lfloor 2\rho \rfloor\) and
\[
\eta_1 < \frac{1}{\rho} - \frac{1}{2}, \quad \eta_2 < \frac{1}{2\rho}, \quad \text{and} \quad \eta_3 < \frac{N + 1}{2\rho} - 1.
\]
Assume that \(|V|_{\text{Lip}}^{\theta} \leq \nu < \infty\) for some \(\theta \in (0,\infty]\) chosen such that \(\theta > \frac{2\rho}{1 - 2\omega} \) and \(\theta \geq N\). Set
\[
D = \{0 < h < 2h < \ldots < ([T/h] - 1)h < T\}
\]
for \(h > 0\). Then for any \(r \geq 1\),
\[
\left| |Y - Y_{\text{simple Euler};D}|_{\infty} \right|_{L^r} \lesssim h^\eta_1 + h^\eta_2 + h^\eta_3
\]
for all \(h > 0\).
Remark 16. In the proof we will see that the rate $\eta_1$ is the rate for the Wong-Zakai approximation, the rate $\eta_2$ comes from the (almost) $\frac{1}{2}$-Hölder-regularity of the sample paths of $Y$ and $\eta_3$ comes from the step-$N$ Euler approximation. Since $\rho \geq 1$, the Wong-Zakai error always dominates $\eta_2$. In particular, for $\rho = 1$ we can choose $N = 2$ to obtain a rate arbitrary close to $\frac{1}{2}$. For $\rho > 1$, the choice $N = 3$ gives a rate of almost $\frac{1}{\rho} - \frac{1}{2}$. In both cases the rate does not increase for larger choices of $N$.

From this remark, we immediately obtain

Corollary 17. Assume that the vector fields $V = (V_1, \ldots, V_d)$ are bounded, $C^\infty$ with bounded derivatives and that the covariance of $X$ has finite mixed $(1, \rho)$-variation for some $\rho < 2$. Then the simplified step-3 Euler scheme (step-2 in the case $\rho = 1$) converges in $L^r$, for any $r \geq 1$, and rate $\frac{1}{\rho} - \frac{1}{2} - \delta$, for any $\delta > 0$, to the solution of the corresponding rough differential equation.

Proof of Theorem 15. Let $X^h$ denote the Gaussian process whose sample paths are piecewise linear approximated at the time points given by $D$ and let $Y^h : [0, T] \rightarrow \mathbb{R}^r$ denote the pathwise solution to the equation

$$dY^h = V(Y^h) dX^h; \quad Y^h_0 = Y_0 \in \mathbb{R}^r.$$ 

Then for any $t_k, t_{k+1} \in D$ we have

$$X^h_{t_k, t_{k+1}} = \frac{1}{k!} X^h_{t_k, t_{k+1}} \cdots X^h_{t_k, t_{k+1}},$$

hence $Y^\text{simple Euler};D = Y^h; \text{Euler};D$ for any $t \in D$ and thus

$$|Y_t - Y^\text{simple Euler};D_t| \leq |Y - Y^h|_\infty + \max_{t_k \in D} |Y^h_{t_k} - Y^h|_\infty$$

if $t \in D$. For $t \notin D$, choose $t_k \in D$ such that $t_k < t < t_{k+1}$. Set $a = \frac{t-t_k}{t_{k+1}-t_k}$ and $b = \frac{t_{k+1}-t}{t_{k+1}-t_k}$. Then $a+b = 1$ and by the triangle in equality,

$$|Y_t - Y^\text{simple Euler};D_t| \leq a |Y_t - Y^h_{t_{k+1}}| + b |Y_t - Y^h_{t_{k}}| + a |Y^h_{t_{k+1}} - Y^\text{simple Euler};D_t|$$

$$+ b |Y^h_{t_k} - Y^\text{simple Euler};D_t| \leq h^{1/p} \|Y\|_{1/p; \text{Hö}} + \max_{t_k \in D} |Y^h_{t_k} - Y^\text{simple Euler};D_t|$$

$$\leq h^{1/p} \left( \|X\|_{1/p; \text{Hö}} \vee \|X\|_{1/p; \text{Hö}}^p \right) + |Y - Y^h|_\infty$$

$$+ \max_{t_k \in D} |Y^h_{t_k} - Y^h|_\infty$$

for any $p > 2\rho$. Since the right hand side does not depend on $t$, we can pass to the sup-norm on the left hand side. We now take the $L^r$-norm on both sides and check that the conditions of Theorem 13 and 10 are fulfilled and that the constants can be chosen independently from $h$. Since we are dealing with piecewise linear approximations, we have

$$\sup_{h>0} V^\rho \left( R(X^h, X); [0, T] \right) < \infty \quad \text{and} \quad \sup_{t \in [0, T]} E \left[ |X^h_t - X_t|^2 \right] \lesssim h^{1/p}$$

(cf. [FV10b Chapter 15]). Furthermore, for every $\omega \in \Omega$ one has $|\omega^h_{p; \text{var}}| \leq 3^{1-1/p} |\omega|_{p; \text{var}}$ and $|\omega^h_{1/p; \text{Hö}}| \leq 3^{1-1/p} |\omega|_{1/p; \text{Hö}}$ for every $p \geq 1$ and $h > 0$ (this follows, for instance, from [FV10b].)
Theorem 5.23]). This shows that we can apply Theorem 13 to see that for any \( \delta > 0 \),
\[
\left\| Y - Y_h \right\|_\infty \lesssim h^{\eta_1}
\]
holds for all \( h > 0 \). Furthermore, can choose \( p' > 2 \) such that \( \frac{N+1}{p'} - 1 = \eta_3 \) and then apply Theorem 10. Since \( \left\| d_{1/p' - Ho}(X^h, X) \right\|_{L^r} \to 0 \) for \( h \to 0 \), clearly \( \sup_{h > 0} \left\| X^h \right\|_{1/p' - Ho; [0,T]} \right\|_{L^r} < \infty \) and the constants on the right hand side can be chosen independently of \( h \). Choosing \( p \) such that \( \frac{1}{p} = \eta_2 \) gives the claim. \( \square \)

3. Multilevel simulation of RDEs

In the spirit of Giles [Gil08b] we consider a multilevel Monte Carlo procedure in connection with the developed schemes for RDEs. In this context we reconsider and refine the complexity analysis by Giles 2008 in certain respects. On the one hand we relax the requirement \( \alpha \geq 1/2 \) in Giles 2008 concerning the bias rate, and on the other we keep track of various proportionality constants more carefully. Naturally, in case one is only interested in achieving asymptotically the desired multilevel complexity rate, one may fix the trade-off between the bias and variance of the estimator, and also one doesn’t need to distinguish between proportionality constants due to the zero-level and the other ones (cf. Giles 2008). However, it so may happen that the proportionality coefficient of the estimated asymptotic complexity is so large that the “critical accuracy” where the multilevel estimator starts outperforming the standard one is too close to zero. For example, for certain RDEs the multilevel complexity rate still contains a relatively high negative power of \( \epsilon \). A too large proportionality constant would then lead to a critical accuracy that cannot be reached within a reasonable computation time by the multilevel estimator and by the standard estimator even more. (Cf. the importance of various proportionality constants in the multilevel Andersen-Broadie algorithm for simulating dual prices of American options due to multilevel sub-simulation in [BSD13].)

We adapt the main theorem of [Gil08b] to our needs. Below one should think
\[
P = f(Y)
\]
for a Lipschitz function \( f \) and \( Y \) the solution to the Gaussian RDE \( dY = V(Y) dX \). Let \( \hat{P}_l \) denote some (modified) Milstein approximation à la [DNT12], for instance (4), based on a meshsize \( h_l = T/(M_0 M^l) \). Recall the basic idea
\[
E[P] \approx E[\hat{P}_L] \text{ for } L \text{ large}
\]
\[
= E[\hat{P}_0] + \sum_{l=1}^{L} E[\hat{P}_l - \hat{P}_{l-1}]
\]
set \( \hat{P}_{-1} \equiv 0 \) and define the (unbiased) estimator \( \hat{Y}_l \) of \( E[\hat{P}_l - \hat{P}_{l-1}] \), say
\[
\hat{Y}_l = \frac{1}{N_l} \sum_{i=1}^{N_l} \left( \hat{P}_l^{(i)} - \hat{P}_{l-1}^{(i)} \right)
\]
(9)
based on \( i = 1, \ldots, N_l \) independent samples. Note that \( \hat{P}_l^{(i)} - \hat{P}_{l-1}^{(i)} \) comes from approximations with different mesh but the same realization of the driving noise.
3.1. Giles' complexity theorem revisited. The following abstract theorem is an extension of [Gil08b] to the case $\alpha < 1/2$, with special consideration of the involved constants.

**Theorem 18.** Let $0 < \alpha < 1/2$ and $0 < \beta \leq 2\alpha$. In the spirit of Giles, we assume that there are constants $c_1$, $c_2$, $c_3$ and $c_4$ such that

(i) $E \left[ \hat{P}_l - P \right] \leq c_1 h_l^\alpha$,

(ii) $E \left[ \hat{Y}_0 \right] = E \left[ \hat{P}_0 \right]$ and $E \left[ \hat{Y}_l \right] = E \left[ \hat{P}_l - \hat{P}_{l-1} \right]$, $l > 0$,

(iii) $\text{var} \left[ \hat{Y}_0 \right] \leq c_2 N_0^{-1}$ and $\text{var} \left[ \hat{Y}_l \right] \leq c_2 N_l^{-1} h_l^\beta$ for $l \in \mathbb{N}$,

(iv) the complexity $C_l$ of computing $\hat{Y}_l$ is bounded by $C_0 \leq c_3 N_0 h_0^{-1}$ for $l = 0$ and $C_l \leq c_3 N_l (h_l^{-1} + h_{l+1}^{-1})$ for $l \geq 1$.

Then for every $\varepsilon > 0$, there are choices $L$ and $N_l$, $0 \leq l \leq L$, to be given below in (13) and (14), respectively, and constants $c_4$ and $c_5$ given in (15) together with (16) such that the multilevel estimator $\hat{Y} = \sum_{l=0}^{L} \hat{Y}_l$ satisfies the mean square error bound

$$\text{MSE} \equiv E \left[ \left( \hat{Y} - E[P] \right)^2 \right] < \varepsilon^2,$$

with complexity bound

$$C \leq \text{const} \varepsilon^{-1+2\alpha-\beta} + o \left( \varepsilon^{-1+2\alpha-\beta} \right),$$

where $\text{const} = c_4$ for $\beta < 2\alpha$ and $\text{const} = c_4 + c_5$ for $\beta = 2\alpha$.

**Proof.** We first ignore the basic requirement of $L$ and $N_l$ being integer values to obtain (almost) optimal real-valued choices for $L$ and $N_l$. Then we are going to verify the above given bounds for the MSE and the complexity using the smallest integers dominating our real-valued choices. In this proof, we abuse notation by setting $T = T/M_0$, noting that both complexity and MSE only depend on $T$ and $M_0$ by $T/M_0$.

The mean-square-error satisfies

$$\text{MSE} = E \left[ \left( \hat{Y} - E[P] \right)^2 \right]$$

$$= E \left[ \left( \hat{Y} - E[\hat{Y}] \right)^2 + \left( E[\hat{Y}] - E[P] \right)^2 \right]$$

$$= \text{var} \left[ \hat{Y} \right] + \left( E[\hat{P}_L] - E[P] \right)^2$$

$$\leq \sum_{l=0}^{L} \text{var} \left[ \hat{Y}_l \right] + c_4^2 h_L^{2\alpha}$$

$$\leq c_2^2 N_0^{-1} + c_2 T^\gamma \sum_{l=1}^{L} N_l^{-1} M^{-l\beta} + c_4^2 h_L^{2\alpha}.$$

---

3. We distinguish between $c_2$ and $c_2$, since the former controls the variance $\text{var} \left[ \hat{Y}_0 \right]$, which is often already proportional to the variance of $f(Y)$, whereas the latter controls the variance of the difference $\hat{Y}_l$, which is often much smaller in size.

4. Note that the complexity at the 0-level is proportional to the number of timesteps $h_0^{-1}$, whereas at higher levels, we need to apply the numerical scheme twice, once for the finer and once for the coarser grid.
Now we need to minimize the total computational work

\[ C \leq c_3 N_0 h_0^{-1} + c_3 \sum_{l=1}^{L} N_l \left( h_l^{-1} + h_{l-1}^{-1} \right) \]

\[ = c_3 T^{-1} \left[ N_0 + \frac{M + 1}{M} \sum_{l=1}^{L} N_l M^l \right] \]

under the constraint \( \text{MSE} \leq \varepsilon^2 \). We first assume \( L \) to be given and minimize over \( N_0, \ldots, N_L \), and then we try to find an optimal \( L \). We consider the Lagrange function

\[ f(N_0, \ldots, N_L, \lambda) \equiv c_3 T^{-1} \left[ N_0 + \frac{M + 1}{M} \sum_{l=1}^{L} N_l M^l \right] + \lambda \left( c_2 N_0^{-1} + c_2 T^\beta \sum_{l=1}^{L} N_l^{-1} M^{-1-\beta} + c_1 h_0^{2\alpha} - \varepsilon^2 \right) \].

Taking derivatives with respect to \( N_l \), \( 0 \leq l \leq L \), we arrive at

\[ \frac{\partial f}{\partial N_0} = c_3 T^{-1} - \lambda c_2 N_0^{-2} = 0, \]

\[ \frac{\partial f}{\partial N_l} = c_3 T^{-1} M^l \frac{M + 1}{M} - \lambda c_2 T^\beta M^{-1-\beta} N_l^{-2} = 0, \]

implying that

\[ N_0 = \sqrt{\lambda} \sqrt{\frac{c_2}{c_3} T}, \]

\[ N_l = \sqrt{\lambda} \sqrt{\frac{c_2}{c_3} T^{(1+\beta)/2}} \sqrt{\frac{M}{M + 1}} M^{-l(1+\beta)/2}, \quad 1 \leq l \leq L, \]

which we insert into the bound for the MSE to obtain

\[ \sqrt{\lambda} = \left[ \sqrt{\frac{c_2}{c_3} T^{-\beta}} + \sqrt{\frac{c_2}{c_3} \sqrt{\frac{M + 1}{M} M^{(1-\beta)/2} \frac{M^L (1-\beta)/2 - 1}{M^{(1-\beta)/2 - 1}}}} \right]^{-1} \left( \frac{1}{\varepsilon^2 - c_1 T^{2\alpha} M^{-2\alpha L}} \right)^{T^{-1}(1-\beta)/2}. \]

By construction, we see that for any such choice of \( N_0, \ldots, N_L \), the MSE is, indeed, bounded by \( \varepsilon^2 \). For fixed \( L \), the total complexity is now given by

\[ C(L) \equiv c_3 T^{-1} \left[ \sqrt{\lambda} \sqrt{\frac{c_2}{c_3} T + \frac{M + 1}{M} \sqrt{\frac{c_2}{c_3} \sum_{l=1}^{L} M^l \sqrt{\lambda} \sqrt{\frac{c_2}{c_3} T^{(1+\beta)/2} \sqrt{\frac{M}{M + 1}} M^{-l(1+\beta)/2}}} \right] \]

\[ = \sqrt{\lambda} T^{-(1-\beta)/2} \left[ \sqrt{\frac{c_2}{c_3} T^{-\beta}} + \sqrt{\frac{c_2}{c_3} \sqrt{\frac{M + 1}{M} M^{(1-\beta)/2} \frac{M^L (1-\beta)/2 - 1}{M^{(1-\beta)/2 - 1}}}} \right] \]

\[ = \left[ \sqrt{\frac{c_2}{c_3} T^{-\beta}} + \sqrt{\frac{c_2}{c_3} \sqrt{\frac{M + 1}{M} M^{(1-\beta)/2} \frac{M^L (1-\beta)/2 - 1}{M^{(1-\beta)/2 - 1}}}} \right]^2 \left( \frac{1}{\varepsilon^2 - c_1 T^{2\alpha} M^{-2\alpha L}} \right)^{T^{-1}(1-\beta)}. \]

In general, the optimal (but real-valued) choice of \( L \) would now be the arg-min of the above function, which we could not determine explicitly in an arbitrary regime. We parametrize the optimal choice...
of $L$ by $d_1$ in
\begin{equation}
L = \left\lceil \frac{\log\left(d_1 c_1 T^{\alpha - 1}\right)}{\alpha \log(M)} \right\rceil.
\end{equation}

There are three different approaches to the choice of $L$: Giles chooses $d_1 = 1/2$, which is probably motivated by the considerations in Remark 20 below. If all the constants involved have already been estimated, then one could choose $L$ by numerical minimization of the complexity, or one could provide an asymptotic optimizer $L$ (for $\varepsilon \to 0$). The latter approach has been carried out for the special case $\beta = 1$ in Theorem 21 below, and in this case the optimal $L$ is indeed (almost) of the form \[(13)\] with $d_1$ weakly depending on $\varepsilon$.

Moreover, we choose with $\kappa = \frac{1-\beta}{2\varepsilon}$
\begin{align}
N_0 &= \left\lceil \frac{\sqrt{c_2} T^\beta}{\varepsilon^2 (1 - d_1^2)} \left( \sqrt{c_2^2} T^{-\beta} + \sqrt{c_2} \sqrt{\frac{M + 1}{M} M^{(1-\beta)/2} \frac{d_1^0 T^{(1-\beta)/2} \varepsilon^{-\kappa} - 1}{M^{(1-\beta)/2} - 1}} \right) \right\rceil, \\
N_l &= \left\lceil \frac{\sqrt{c_2} T^\beta}{\varepsilon^2 (1 - d_1^2)} \left( \sqrt{c_2^2} T^{-\beta} + \sqrt{c_2} \sqrt{\frac{M + 1}{M} M^{(1-\beta)/2} \frac{d_1^0 T^{(1-\beta)/2} \varepsilon^{-\kappa} - 1}{M^{(1-\beta)/2} - 1}} \right) M^{-l(1+\beta)/2} \right\rceil,
\end{align}
$1 \leq l \leq L$.

By construction, the MSE will be bounded by $\varepsilon^2$ using the choices \[(13)\] and \[(14)\]. As $x \leq \lceil x \rceil \leq x + 1$ and using the inequalities
\begin{align*}
M^L &\leq d_1^{1/\alpha} c_1^{1/\alpha} T M \varepsilon^{-1/\alpha}, \\
M^{L(1-\beta)/2} &\leq d_1^{\kappa} c_1^{(1-\beta)/2} M^{(1-\beta)/2} \varepsilon^{-\kappa},
\end{align*}

together with the shorthand-notations
\begin{align*}
e_1 &= \sqrt{c_2} T^{-\beta} - \sqrt{c_2} \sqrt{\frac{M + 1}{M} M^{(1-\beta)/2} - 1}, \\
e_2 &= d_1^{\kappa} c_2^{(1+\beta)/2} \sqrt{\frac{M + 1}{M} M^{(1-\beta)/2} - 1} T^{(1-\beta)/2},
\end{align*}
motivated from our choice \[(14)\], we arrive after a tedious calculation at
\begin{align*}
C &\leq c_3 T^{-1} \left[ N_0 + \frac{M + 1}{M} \sum_{l=1}^{L} N_l M^l \right] \\
&\leq c_3 T^{-1} \left[ 1 + \sqrt{c_2} T^\beta (1 - d_1^{-2})^{-1} (e_1 + e_2 \varepsilon^{-\kappa}) \varepsilon^{-2} + \\
&\quad + \sqrt{c_2} T^\beta (1 - d_1^{-2})^{-1} \sqrt{\frac{M + 1}{M} M^{(1-\beta)/2} - 1} \left( d_1^{\kappa} c_1^{(1-\beta)/2} M^{(1-\beta)/2} \varepsilon^{-\kappa} - 1 \right) (e_1 + e_2 \varepsilon^{-\kappa}) \varepsilon^{-2} + \\
&\quad + \frac{M + 1}{M - 1} \left( d_1^{1/\alpha} c_1^{1/\alpha} T M \varepsilon^{-1/\alpha} - 1 \right) \right].
\end{align*}
Arranging the terms according to powers of \( \varepsilon \) and recalling \( \kappa = \frac{1-\beta}{2\alpha} \), we get
\[
C \leq c_4 \varepsilon^{-2(1+\kappa)} + c_5 \varepsilon^{-1/\alpha} + c_6 \varepsilon^{-(2+\kappa)} + c_7 \varepsilon^{-2} + c_8,
\]
where
\[
\begin{align*}
(16a) & \quad c_4 = c_1 c_2^{1+\kappa} c_3 \frac{d_1^{2\kappa}}{1 - d_1^2} \frac{M + 1}{M} \frac{M^{3(1-\beta)/2}}{(M^{1-\beta}/2 - 1)^2}, \\
(16b) & \quad c_5 = c_1^{1/\alpha} c_3 d_1^{1/\alpha} \frac{M(M + 1)}{M - 1}, \\
(16c) & \quad c_6 = (c_1^{\kappa} + c_2^{\kappa}) \sqrt{c_2 c_3} \frac{d_1^{2\kappa}}{1 - d_1^2} T^{-(1-\beta)/2} \sqrt{\frac{M + 1}{M}} \frac{M^{1-\beta}/2}{M^{1-\beta}/2 - 1}, \\
(16d) & \quad c_7 = \frac{c_3 T^{-(1-\beta)}}{1 - d_1^2} c_1^{\kappa}, \\
(16e) & \quad c_8 = -\frac{2 c_3 T^{-1}}{M - 1}.
\end{align*}
\]

We remark that, under the condition that \( \beta \leq 2\alpha \), we have \( 2(1 + \kappa) \geq 1/\alpha \) with equality iff \( \beta = 2\alpha \). Consequently, \( \varepsilon^{-2(1+\kappa)} \) is the dominating term in the complexity-expansion. We further note that the second term in the expression can be either \( \varepsilon^{-1/\alpha} \) or \( \varepsilon^{-(2+\kappa)} \).

The leading order coefficients \( c_4 \) and \( c_5 \) are positive, whereas the sign of \( c_6 \) is not clear. In particular, if we do not distinguish between the variance of \( \bar{Y}_0 \) (controlled by \( c'_2 \)) and the variances of the differences \( \bar{Y}_l, l = 1, \ldots, L \), controlled by \( c_2 \), then \( c_6 \) will be negative. \( c_7 \) is again positive (but often small) and \( c_8 \) is negative. Clearly, we could simplify the complexity bound by omitting all terms with negative coefficients in (15). We further note that the leading order terms of the complexity do not depend on \( T \) or \( M_0 \).

We do not know the rate of weak convergence \( \alpha \) of our simplified Milstein scheme, but for Lipschitz functions \( f \), we clearly have
\[
|E[f(X) - f(Y)]| \leq |f|_{\text{Lip}} E[|X - Y|_\infty],
\]
so that the weak rate of convergence is at least as good as the strong rate of convergence, i.e., \( \alpha \geq \beta/2 \) in the above notation. In fact, if we only impose minimal regularity conditions on \( f \), then it is highly unlikely that we can get anything better than \( \alpha = \beta/2 \).

**Corollary 19.** Under the assumptions of Theorem 18, let us additionally assume that \( \alpha = \beta/2 \). Then the complexity of the above multi-level algorithm is bounded by
\[
C \leq c'_4 \varepsilon^{-1/\alpha} + o \left( \varepsilon^{-1/\alpha} \right),
\]
where
\[
c'_4 = c_3 d_1^{1/\alpha} (M + 1) \left[ \frac{c_1^{(1-\beta)/\beta} c_2^{1/\beta}}{d_1^2 - 1} \frac{M^{3(1-\beta)/2}}{M (M^{1-\beta}/2 - 1)^2} + \frac{2}{M - 1} \right].
\]
The optimal choice of $d_1$ minimizing $c'_4$ is obtained by
\[
d_1 = \sqrt{1 - \frac{(1 - \beta)f_1}{2f_2} + \frac{\sqrt{(1 - \beta)^2f_1^2 + 4\beta f_1f_2}}{2f_2}},
\]
with
\[
f_1 = c_1^{(1-\beta)/\beta} c_2^{1/\beta} c_3^{M+1} M \frac{M^{3(1-\beta)/2}}{(M(1-\beta)/2 - 1)^2},
\]
\[
f_2 = c_1^{2/\beta} c_3^{M(M+1)} M^{-1}.
\]

**Proof.** We use $c'_4 = c_4 + c_5$ in order to obtain the formula for the constant. Then we consider $c'_4$ as a function of $d_1$ and get the minimizer as the unique zero of the derivative in $]1, \infty[$, noting that $c'_4$ approaches $\infty$ on both boundaries of the domain. \qed

**Remark 20.** In the now classical works of Giles on multilevel Monte Carlo, he usually chooses $d_1 = \sqrt{2}$, see for instance [Gil08b]. This means that we reserve the same error tolerance $\varepsilon/2$ both for the bias or discretization error and for the statistical or Monte Carlo error. In many situations, this choice is not optimal. In fact, even in an ordinary Monte Carlo framework, one should not blindly follow this rule.

For instance, for an SDE driven by a Brownian motion, the Euler scheme usually (i.e., under suitable regularity conditions) exhibits weak convergence with rate $1$. Assuming the same constants for the weak error and the statistical error, a straightforward optimization will show that it is optimal to choose the number of timesteps and the number of Monte Carlo samples such that the discretization error is $\varepsilon/3$ and the statistical error is $2\varepsilon/3$.

In the above, the choice of $d_1$ corresponds to the distribution of the total MSE $\varepsilon^2$ between the statistical and the discretization error according to
\[
\varepsilon^2 = \underbrace{\varepsilon^2 \frac{c_2^2 T^2}{d_1^2}}_{\text{disc. error}} + \underbrace{\left(1 - \frac{1}{d_1^2}\right)\varepsilon^2}_{\text{stat. error}}.
\]
So, depending on the parameters, Corollary 19 shows that the canonical error distribution is not optimal.

As the leading order coefficients $c'_4$ depends only mildly on $M$, we do not try to find an optimal choice of the parameter $M$.

The above analysis has also given us new insight into the classical multi-level Monte Carlo algorithm corresponding to the choice $\beta = 1$. Indeed, even in this case an equal distribution of the error tolerance $\varepsilon$ among the bias and the statistical error is far from optimal. Indeed, we have

**Theorem 21.** For $\beta = 1$ and $\alpha \geq 1/2$, the optimal choice of $L$ is (apart from rounding up) given by
\[
L(\varepsilon) = \frac{1}{\alpha \log M} \log \left[ \varepsilon^{-1} \left( c_1^2 T^{2\alpha} \left(1 + \sqrt{\frac{c_2^2 M}{c_2 T^2 (M+1) \alpha \log M}} \right) + c_1^2 T^{2\alpha} \log \varepsilon^{-1} \right)^{1/2} \right] + O\left(\frac{\log \log \varepsilon^{-1}}{\log \varepsilon^{-1}}\right),
\]
which is of the form (13) with

\[
d_1 \approx \left(1 + \sqrt{\frac{c'_2}{c_2 T}} \frac{M}{M + 1} \alpha \log M + \log \varepsilon^{-1}\right)^{1/2}.
\]

**Proof.** Let us investigate the behaviour of (12) for \(\beta \uparrow 1\). For \(\beta \uparrow 1\) we obtain

\[
C^{\beta=1}(L) = \left[\sqrt{c'_2 c_3 T^{-1}} + \sqrt{c_2 c_3} \sqrt{\frac{M + 1}{M}} L\right]^2 \frac{1}{\varepsilon^2 - \varepsilon^{-2}} M^{-2aL},
\]

and we want to minimize this object for \(L\). Let us abbreviate to

\[
D(L) := \frac{C(L)}{c'_2 c_3 T^{-1}} = (1 + aL)^2 \frac{1}{\varepsilon^2 - bM^{-cL}}
\]

with obvious definitions for \(a, b, c\). Setting the derivative to zero yields

\[
D'(L) = 2a (1 + aL) \frac{1}{\varepsilon^2 - bM^{-cL}} - (1 + aL)^2 \frac{bcM^{-cL} \log M}{(\varepsilon^2 - bM^{-cL})^2} = 0
\]

i.e.

\[
2a (\varepsilon^2 - bM^{-cL}) = (1 + aL) bcM^{-cL} \log M
\]

\[
2a \varepsilon^2 M^{cL} = 2ab + bc \log M + abcL \log M
\]

abbreviate again

\[
\varepsilon^2 M^{cL} = b + \frac{bc}{2a} \log M + \frac{bc}{2} L \log M =: p + qL
\]

and write the latter as

\[
M^{cL} = \frac{p + qL}{\varepsilon^2}
\]

We now derive an asymptotic expansion for the solution \(L(\varepsilon)\) to (18) for \(\varepsilon \downarrow 0\). For this we take the logarithm of (18) to obtain with \(y := \log \varepsilon^{-2}\) (with \(y \to \infty\) as \(\varepsilon \downarrow 0\)).

\[
L = \frac{y}{c \log M} + \frac{\log (p + qL)}{c \log M}.
\]

By reformulating (19) as

\[
L = \frac{y}{c \log M} + \frac{1}{c \log M} \left(\log L + \log q + \log \left(\frac{p}{qL} + 1\right)\right)
\]

\[
= \frac{y}{c \log M} + \frac{\log q}{c \log M} + \frac{\log L}{c \log M} + O(L^{-1}),\quad y \to \infty,
\]

and then writing (20) as

\[
L = \frac{y}{c \log M} + \frac{\log q}{c \log M} + O(L^{-1})
\]

\[
1 - \frac{\log L}{c \log M}
\]

we easily observe that \(L = O(y)\) as \(y \to \infty\). We thus get by iterating (19),

\[
L = \frac{y}{c \log M} + O(\log y),
\]
and iterating once again,

\[
L = \frac{y}{c \log M} + \log \left( p + \frac{qu}{c \log M} + O\left( \log y \right) \right) + O\left( \frac{\log y}{y} \right),
\]

The next few iterations yield

\[
L = \frac{y}{c \log M} + \frac{\log \left( p + \frac{qu}{c \log M} + \frac{q \log \left( p + \frac{qu}{c \log M} \right)}{c \log M} \right)}{c \log M} + O\left( \frac{\log y}{y^2} \right),
\]

etc. After re-expressing the asymptotic solution in the original terms via

\[
a = \sqrt{\frac{c_2 M + 1}{M}} T,
\]
\[
b = c_1^2 T^{2\alpha},
\]
\[
p = c_1^2 T^{2\alpha} \left( 1 + \sqrt{\frac{c_2}{c_2^2 T M + 1}} \alpha \log M \right)
\]
\[
q = c_1^2 \alpha T^{2\alpha} \log M
\]

we gather, respectively,

\[
L(\varepsilon) = \frac{\log \varepsilon^{-1}}{\alpha \log M} + O\left( \frac{\log \log \varepsilon^{-1}}{\alpha \log M} \right),
\]

\[
L(\varepsilon) = \frac{1}{\alpha \log M} \log \varepsilon^{-1}
\]
\[
+ \frac{1}{2\alpha \log M} \log \left( c_1^2 T^{2\alpha} \left( 1 + \sqrt{\frac{c_2}{c_2 T M + 1}} \alpha \log M \right) + c_1^2 T^{2\alpha} \log \varepsilon^{-1} \right)
\]
\[
+ O\left( \frac{\log \log \varepsilon^{-1}}{\log \varepsilon^{-1}} \right)
\]

etc. The resulting complexity \([12]\) will be obviously

\[
C^{\beta=1}(L) = O\left( \frac{\log^2 \varepsilon^{-1}}{\varepsilon^2} \right),
\]
where sharper expressions can be obtained by inserting one of the above asymptotic expansions for $L(\varepsilon)$. Note that (21) may be written as

$$L(\varepsilon) = \frac{1}{\alpha \log M} \log \left[ \varepsilon^{-1} \left( c_2 T^{2\alpha} \left( 1 + \sqrt{\frac{c_2}{c_2 T M + 1} \alpha \log M} \right) + c_2 T^{2\alpha} \log \varepsilon^{-1} \right)^{1/2} \right]$$

and

$$+ O\left( \frac{\log \log \varepsilon^{-1}}{\log \varepsilon^{-1}} \right)$$

which suggest that in (13),

$$d_1 \approx \left( 1 + \sqrt{\frac{c_2}{c_2 T M + 1} \alpha \log M + \log \varepsilon^{-1}} \right)^{1/2}$$

for the case $\beta = 1$. □

Table 1. Comparison of asymptotic complexity for multilevel and standard Monte Carlo in the framework of Theorem 18. $\alpha$ denotes the weak order of convergence, $\beta/2$ the strong order. We distinguish the cases $\alpha = \beta/2$ and $\alpha = \beta$.

Under the assumptions of Theorem 18, we can summarize the complexity requirements for the multi-level and the classical Monte Carlo methods, respectively, to obtain an MSE of order $\varepsilon^2$, see Table 1. In particular, note that the complexity of classical Monte Carlo is asymptotically worse by a factor $\varepsilon^{-2}$ in the “non-regular” case, when the weak rate is equal to the strong rate, but still worse by a factor $\varepsilon^{-1}$ when the weak rate is actually twice as good as the strong rate.

### 3.2. Multilevel Monte Carlo for RDEs

Let $X: [0, T] \to \mathbb{R}^d$ be Gaussian with the same assumptions as in Theorem 10 for some $\rho \in [1, 2)$. Consider the solution $Y: [0, T] \to \mathbb{R}^m$ of the RDE

$$dY_t = V(Y_t) \, dX_t; \quad Y_0 \in \mathbb{R}^m$$

where $V = (V_1, \ldots, V_d)$ is a collection of vector fields in $\mathbb{R}^m$ with $|V|_{\text{Lip}} < \infty$ for some $\gamma \geq \frac{2\rho}{\rho-1}$.

Set $S := Y$ and let $S^{(h_i)}$ be the simplified step-3 Euler approximation of $Y$ with mesh-size $h_i$ (in the case $\rho = 1$, it suffices to consider a step-2 approximation). Let $f: C([0, T], \mathbb{R}^m) \to \mathbb{R}^n$ be a Lipschitz continuous functional and set $P := f(S)$, $\hat{P}_i := f(S^{(h_i)})$. We want to calculate the quantities needed in Theorem 18. It suffices to apply the modified complexity theorem with $\alpha = \beta/2$. To wit,

$$\text{var} \left[ \hat{P}_i - P \right] \leq E \left[ \left( \hat{P}_i - P \right)^2 \right] \leq \|f\|^2_{\text{Lip}} E \left[ \left| S^{(h_i)} - S \right|^2 \right] = O \left( h_i^2 \right)$$

and

$$\text{var} \left[ \hat{P}_i - \hat{P}_{i-1} \right] \leq \left( \text{var} \left[ \hat{P}_i - P \right]^{1/2} + \text{var} \left[ \hat{P}_{i-1} - P \right]^{1/2} \right)^2 = O \left( h_i^2 \right)$$
for all $\beta < \frac{2}{\rho} - 1$. Of course the variance of the average of $N_l$ IID samples becomes

$$\text{var} \left[ \hat{Y}_l \right] = \frac{1}{N_l} \text{var} \left[ \hat{P}_l - \hat{P}_{l-1} \right] = O \left( \frac{h_l^\beta}{N_l} \right).$$

This shows (iii). Trivially, a strong rate is also a weak rate, in the sense that

$$E \left( \hat{P}_l - P \right) \leq E \left[ \left( \hat{P}_l - P \right)^2 \right]^{1/2} = O \left( \frac{h_l^\beta/2}{N_l} \right).$$

Condition (ii), “unbiasedness” is obvious for the estimator (9). Theorem 15 and 19 then imply

**Theorem 22.** The Monte Carlo evaluation of a functional of an RDE driven by Gaussian signal, to within a MSE of $\varepsilon^2$, can be achieved with computational complexity

$$O \left( \varepsilon^{-\theta} \right) \forall \theta > \frac{2\rho}{2 - \rho}.$$  

**Remark 23.** In the context of an RDE driven by fractional Brownian motion, the condition (iv) of Theorem 18 is not precisely satisfied, as there seems no exact simulation algorithm for increments of a fractional Brownian motion with linear complexity, see [Die04]. There are inexact simulation algorithms satisfying (iv), but those would introduce additional error terms in the other conditions. On the other hand, there are exact simulation algorithms with “almost linear” complexity, i.e., linear complexity up to logarithmic terms. Obviously, these logarithmic terms would propagate into the complexity statement of Theorem 18. However, Theorem 22 above remains unchanged, due to the “$\delta > 0$”-term inherited from Corollary 17.

In Table 2 we compare typical asymptotic complexities for RDEs driven by fractional Brownian motion for both the multi-level and the classical Monte Carlo estimators. We distinguish between the “non-regular” regime when $\alpha = \beta/2$ and the more favorable regime when $\alpha = \beta$. Moreover, we have simplified the presentation in Table 2 by neglecting the higher order terms. I.e., any complexity $\varepsilon^{-a}$ in Table 2 should actually be understood as $\varepsilon^{-a-\delta}$ for any $\delta > 0$. Thus, when the Hurst parameter is not too small, multi-level can make the difference between a feasible simulation and a quite impossible one. E.g., when $H = 2/5$ and the payoff function $f$ is so irregular that the weak rate of convergence is not better than the strong rate of convergence, the complexity for a standard Monte Carlo estimator would be roughly of order $\varepsilon^{-5.33}$, whereas the multi-level version would have complexity roughly of order $\varepsilon^{-3.33}$, which is not much worse than the complexity of a standard Monte Carlo estimator of the usual Brownian motion regime. Admittedly, when $H = 1/3$ and one has an irregular payoff, then the complexity of both standard and multi-level Monte Carlo are probably too bad for many situations.

4. **Numerical experiments**

We consider a linear RDE in $\mathbb{R}^3$ driven by a two-dimensional fractional Brownian motion with Hurst index $H$. In fact, we consider vector fields $V_i(y) = A_i y$, $y \in \mathbb{R}^3$, $i = 1, 2$, with

$$A_1 = \begin{pmatrix} 0 & 1 & 2 \\ -1 & 0 & 1/2 \\ -2 & -1/2 & 0 \end{pmatrix}, \quad A_2 = \begin{pmatrix} 0 & 0.7 & 0.9 \\ -0.7 & 0 & 1 \\ -0.9 & -1 & 0 \end{pmatrix}.$$  

Note that the matrices $A_1$ and $A_2$ are anti-symmetric, implying that the sphere $S^2$ is invariant under the solution of the SDE. We implement the simplified Euler scheme (4), where the increments
of the fractional Brownian motion were simulated by Hosking’s method, see [Die04] \footnote{The underlying Gaussian random numbers are simulated using the Box-Müller method. The pseudo random numbers are generated by the Mersenne-Twister [MN98].}. Hosking’s method is an exact simulation method, i.e., if fed with truly Gaussian random numbers, it will produce samples from the true distribution of increments of the fractional Brownian motion. It is similar to the more obvious simulation method based on the Cholesky factorization of the covariance matrix of the increments, but preferable in terms of memory requirement, especially when grids of sizes of up to $2^{14} = 16384$ are considered. As Cholesky’s method, the complexity of simulating the increments of the fractional Brownian motion on a grid with size $M$ is essentially proportional to $M^2$. There are non-exact methods with linear complexity, and even exact methods with linear complexity up to logarithmic terms, but we prefer Hosking’s algorithm due to its simplicity.

In practice, this means that we generated the increments of the fBM $X$ on the finer grid \( \frac{N}{2^k}, k = 0, \ldots, 2N \) and then obtained the increments on the coarser grid by adding the respective increments on the fine grid.

### Table 2. Comparison of asymptotic complexities for multi-level and classical Monte Carlo for RDEs driven by fractional Brownian motion with Hurst index $H = 2/5$ and $H = 1/3$. We distinguish between the cases $\alpha = \beta/2$ and $\alpha = \beta$.

For this summary, we neglect the “higher order terms”, i.e., we neglect the $\delta$ in $\beta/2 = 1/\rho - 1/2 - \delta$. For $H = 2/5$, we set $\beta/2 = 3/10$, and for $H = 1/3$ we set $\beta/2 = 1/6$.
Figure 1. Strong and weak error for a fBM with Hurst index $H = 0.4$. Dashed line corresponds to the theoretical strong rate of convergence $0.3$, dotted lines show confidence intervals around the error due to the integration error. Weak error corresponds to the functional $f(y) := (|y(1)| - 1)^+$. are even larger than for $H = 0.4$, and, moreover, the pre-asymptotic phase seems even longer: here the mesh of the grid should probably be at least $0.01$ in order to describe the true computational error by the asymptotic error bounds.
Figure 2. Strong and weak error for a fBM with Hurst index $H = 0.33$. Dashed line corresponds to the theoretical strong rate of convergence 0.16, dotted lines show confidence intervals around the error due to the integration error. Weak error corresponds to the functional $f(y) := (|y(1)| - 1)^+$. This long pre-asymptotic phase, in which the computational error is very large, needs to be taken into account when constructing a successful multi-level estimator: indeed, it is advisable to choose the coarsest grid used in the multi-level iteration already within the asymptotic regime. Thus, in the case $H = 0.4$, we would recommend to choose $h_0 \leq 0.02$ for this particular example.
This is remarkably different from the standard SDE case, where often $h_0$ is chosen to be equal to $T$, i.e., the coarsest grid contains only the start and end points of the interval $[0, T]$. However, when employing this strategy for the fBM example here, the constants in the error bound for the multi-level estimator will completely overshadow the asymptotic convergence rate, to the extent that even for long computation time no “empirical” convergence is exhibited. Indeed, the coarsest levels then combine a large error with an even larger variance, and this combination, while harmless in the asymptotic limit $\varepsilon \to 0$, renders the standard multi-level construction useless.

Fortunately, the picture is completely different when the coarsest grid is chosen to be fine enough, in the current example for $H = 0.4$ this means $h_0 \leq 0.02$. Then the multi-level algorithm requires considerably less computational time for the same MSE tolerance than a classical MC estimator, even for quite moderate levels of the tolerance. For this demonstration, we choose a different function, namely

$$g(y) = |y|1_{y > 0}.$$ 

Indeed, the previously used function $f(y) = (|y| - 1)^+$ has the property that $f(Y_1) \equiv 0$, so that the variance of $f(\overline{Y}_N)$ goes to 0 when $N \to \infty$. This, however, makes the basic idea of the multi-level approach redundant, as the variance of estimators anyway decrease when the mesh is decreased, even without the telescoping procedure.

A direct comparison of the performance of the classical and the multi-level Monte-Carlo estimator is difficult in our situation, as it is very hard to obtain a reference value, i.e., a “true result”. Moreover, by the same reasoning the coefficients $c_i$ in Theorem 18 are very difficult to estimate. Thus, we use the following procedure to test the respective performances:

- Fix $L$, the number of levels in the multi-level procedure, and $h_0$, the coarsest grid. Here, we choose $h_0 = 1/64$ and $L = 7$. Thus, the finest grid in the multi-level Monte Carlo corresponds to $h_L = 0.00012 = 1/8192$. As the fixed $L$ is probably sub-optimal, this choice is disadvantageous to the multi-level algorithm. We also choose the multiplication factor $M = 2$ here, and we parametrize the number of paths $N_l$ for the level $l$ by the number of paths $N_0$ at the coarsest level by some heuristic. In Table 3, we choose $N_0 = 100$. Again, these non-optimal choices favour the classical Monte Carlo estimator.

- Choose the mesh of the classical Monte Carlo estimator to be equal to $h_L$, the finest grid in the multi-level hierarchy. This guarantees that both estimators have the same bias – even though we cannot easily estimate this bias due to the absence of a reference value.

- Choose the number of paths in the classical Monte Carlo estimator and the number of paths in the coarsest grid for the multi-level estimator such that the complexity for the classical Monte Carlo estimator is equal to the complexity of the multi-level Monte Carlo estimator. We use an a-priori estimate for the complexity.
  - For the classical Monte Carlo method, the complexity is estimated by the number of trajectories multiplied by the size of the grid.
  - For the multi-level Monte Carlo method, the complexity at a level $l$ is estimated by the product of the size of the finer grid and the number of trajectories for the level. The overall complexity is estimated by the sum of these complexity estimates for the individual levels.

Note that in practice, this complexity estimate is only given up to a constant of proportionality, which can be checked by comparing run-times on a computer.

- Compute the sample variance for both estimators. If the sample variance for the multi-level Monte Carlo estimator is (significantly) smaller than the sample variance for the
classical Monte Carlo estimator, then we, indeed, have demonstrated that the multi-level
estimator will have a smaller MSE than the classical Monte Carlo estimator given the same
computational budget, i.e., the same complexity.

The nice aspect of this procedure is that it allows a reliable comparison of MSE given a certain
complexity, even when the true MSE is not known because of the absence of a reference value.
However, we stress again that the multi-level estimator constructed above will certainly not be
optimal. In order to take care of the constant in the complexity bound, we also compare the actual
run-times as empirical complexity estimates.

Table 3. Variance and run-times for the multi-level and the classical Monte Carlo
algorithm for fixed complexity and bias. Calculations are normalized by $N_0 = 100$.

Table 3 finds that for comparable complexity the variance associated to the classical Monte
Carlo estimator is considerably lower than the variance of the classical Monte Carlo estimator. It is
interesting to note that the classical Monte Carlo estimator takes considerably longer computational
time. The reason is that the multi-level algorithm uses the Euler scheme on coarser grids on average
than the classical Monte Carlo algorithm. As the complexity for sampling the increments of the
fractional Brownian motion increases quadratically in the size of the grid when Hosking’s method
is applied, this explains why the computational time is almost four times larger for the classical
Monte Carlo method. Note that there are other exact simulation methods with a complexity
of order $O(M \log(M))$ in the grid size $M$, and approximate simulation methods even with order
$O(M)$, see [Die04]. However, at least for the present, linear differential equation, the simulation of
the increments of the fBM will always dominate the Euler steps, even when the complexity does
only increase linearly. Thus, the conclusions of Table 3 should hold irrespective of the simulation
method.

APPENDIX A. RECALLS ON RDEs DRIVEN BY GAUSSIAN SIGNALS

In this section, we introduce the concepts and definitions from rough path theory that are
necessary for our current application. For a detailed account of the theory, we refer readers to
[FV10b], [LCL07] and [LQ02].

Fix the time interval $[0, T]$. For all $s < t \in [0, T]$, let $\Delta_{s,t}$ denote the simplex
\[
\{(u_1, u_2) \mid s \leq u_1 \leq u_2 \leq t\},
\]

7The following heuristic calculation also supports this conclusion: assuming that we replace Hosking’s algorithm
by an algorithm with linear complexity and the same constant. Then we can easily predict the run-time of the
classical Monte Carlo algorithm by dividing the run-time reported in Table 3 by the size of the (finest) grid, i.e., by
8192, which gives a predicted run-time of 0.00045 seconds. For the multi-level Monte Carlo method, the corresponding
factor would be (with $M_t = T h_t^{-1}$ and $N_t = N_0 2^{-((1+\beta)/2)} = N_0 2^{-0.81}$)
\[
\frac{M_2^2 N_0 + \cdots + M_L^2 N_L}{M_0 N_0 + \cdots + M_L N_L} = 2799,
\]
giving a predicted run-time of 0.00035 seconds, which is still lower than the predicted run-time for the classical Monte
Carlo algorithm.
and we simply write $\Delta$ for $\Delta_{0,T}$. In what follows, we will use $x$ to denote an $\mathbb{R}^d$-valued path, and $X$ to denote a stochastic process in $\mathbb{R}^d$, which is a Gaussian process in the current paper. Let $(E, d)$ be a metric space and $x \in C([0, T], E)$. For $p \geq 1$, we define

$$
\|x\|_{p-var; [s,t]} := \sup_{D \subseteq [s,t]} \left( \sum_{t_i, t_{i+1} \in D} |d(x_{t_i}, x_{t_{i+1}})|^p \right)^{\frac{1}{p}}
$$

and

$$
\|x\|_{Hölder; [s,t]} := \sup_{(u,v) \in \Delta_{s,t}} \frac{d(x_u, x_v)}{|u-v|^\frac{1}{p}}.
$$

We will use the short hand notation $\|\cdot\|_{p-var}$ and $\|\cdot\|_{Hölder}$ for $\|\|_{p-var; [0,T]}$ resp. $\|\|_{Hölder; [0,T]}$ which are easily seen to be semi-norms. Given a positive integer $N$ the truncated tensor algebra of degree $N$ is given by the direct sum

$$
T^N(\mathbb{R}^d) = \mathbb{R} \oplus \mathbb{R}^d \oplus \ldots \oplus (\mathbb{R}^d)^\otimes N.
$$

With tensor product $\otimes$, vector addition and usual scalar multiplication, $T^N(\mathbb{R}^d) = (T^N(\mathbb{R}^d), \otimes, +, .)$ is an algebra. Let $\pi_i$ denote the canonical projection from $T^N(\mathbb{R}^d)$ onto $(\mathbb{R}^d)^\otimes i$.

For a path $x : [0, 1] \to \mathbb{R}^d$ of bounded variation, we define the canonical lift $\mathbf{x} = S_N(x) : [0, T] \to T^N(\mathbb{R}^d)$ via iterated (Young) integration,

$$
\mathbf{x}_t \equiv S_N(x)(t) = 1 + \sum_{i=1}^N \int_{0<s_1<\ldots<s_i<t} dx_{s_1} \otimes \ldots \otimes dx_{s_i},
$$

noting that $\mathbf{x}_0 = 1 + 0 + \ldots + 0 = : e$ is the neutral element for $\otimes$, and that $\mathbf{x}_t$ really takes values in

$$
G^N(\mathbb{R}^d) = \{ g \in T^N(\mathbb{R}^d) : \exists x \in C^{1-var}([0, T], \mathbb{R}^d) : g = S_N(X)(1) \},
$$

a submanifold of $T^N(\mathbb{R}^d)$, called the free step-$N$ nilpotent Lie group with $d$ generators. We will use the canonical notion of increments expressed by

$$
\mathbf{x}_{s,t} := \mathbf{x}_s^{-1} \otimes \mathbf{x}_t.
$$

The dilation operator $\delta : \mathbb{R} \times G^N(\mathbb{R}^d) \to G^N(\mathbb{R}^d)$ is defined by

$$
\pi_i(\delta^t(g)) = \lambda^i \pi_i(g), \ i = 0, \ldots, N.
$$

The Carnot-Caratheodory norm, given by

$$
\|g\| = \inf \{ \text{length}(s) : x \in C^{1-var}([0, 1], \mathbb{R}^d), S_N(x)(1) = g \}
$$

defines a continuous norm on $G^N(\mathbb{R}^d)$, homogeneous with respect to $\delta$. This norm induces a (left-invariant) metric on $G^N(\mathbb{R}^d)$ known as Carnot-Carathéodory metric,

$$
d(g, h) := \|g^{-1} \otimes h\|.
$$

Let $x, y \in C_0([0, T], G^N(\mathbb{R}^d))$, the space of continuous $G^N(\mathbb{R}^d)$-valued paths started at the neutral element. We define $p$-variation- and $\frac{1}{p}$-Hölder-distances by

$$
d_{p-var}(x, y) := \sup_{D \subseteq [0, T]} \left( \sum_{t_i, t_{i+1} \in D} |d(x_{t_i}, x_{t_{i+1}})|^p \right)^{\frac{1}{p}}
$$

and

$$
d_{\frac{1}{p}-Hölder}(x, y) := \sup_{(s,t) \in \Delta} \frac{d(x_s, y_s, x_t, y_t)}{|t-s|^{\frac{1}{p}}}.
$$
Note that $d_{\frac{1}{2}-H^\text{Hol}}(x, 0) = \|x\|_{\frac{1}{2}-H^\text{Hol}}$ and $d_{p-\text{var}}(x, 0) = \|x\|_{p-\text{var}}$ where 0 denotes the constant path equal to the neutral element. These metrics are called *homogeneous* rough paths metrics. We define the following path spaces:

(i) $C^0_{p-\text{var}}([0, T], G^N(\mathbb{R}^d))$: the set of continuous functions $x$ from $[0, T]$ into $G^N(\mathbb{R}^d)$ such that $\|x\|_{p-\text{var}} < \infty$ and $x_0 = e$.

(ii) $C^0_{\alpha-H^\text{Hol}}([0, T], G^N(\mathbb{R}^d))$: the set of continuous functions $x$ from $[0, T]$ into $G^N(\mathbb{R}^d)$ such that $\|x\|_{\alpha-H^\text{Hol}} < \infty$ and $x_0 = e$.

(iii) $C^0_{p-\text{var}}([0, T], G^N(\mathbb{R}^d))$: the $d_{p-\text{var}}$-closure of

$$\{ S_N(x), x : [0, T] \to \mathbb{R}^d \text{ smooth} \}.$$ 

(iv) $C^0_{\alpha-H^\text{Hol}}([0, T], G^N(\mathbb{R}^d))$: the $d_{\alpha-H^\text{Hol}}$-closure of

$$\{ S_N(x), x : [0, T] \to \mathbb{R}^d \text{ smooth} \}.$$ 

If $N = |p|$, the elements of the spaces (i) and (ii) are called *weak geometric* (Hölder) rough paths, the elements of (iii) and (iv) are called *geometric* (Hölder) rough paths. Recall that if $V = (V_i)_{i=1, \ldots, d}$ is a collection of $\text{Lip}^\gamma(\mathbb{R}^\gamma)$ vector fields (in the sense of Stein, cf. [FV10b]) for some $\gamma > p$ and $x$ is a $p$-rough path, one can make sense of a unique solution $y$:

$$d y_t = V(y_t) \, d x_t; \quad y_0 \in \mathbb{R}^e.$$ 

In this article, we will mainly be interested in *inhomogeneous* rough paths metrics which we aim to define now. First recall that a *control* is a function $\omega : \Delta \to \mathbb{R}_+$ which is continuous and super-additive in the sense that for all $s \leq u \leq t$ one has

$$\omega(s, u) + \omega(u, t) \leq \omega(s, t).$$

If $\omega$ is a control, we define

$$\|x\|_{p-\omega;[s, t]} := \sup_{s \leq u < v \leq t} \frac{\|x_{u,v}\|}{\omega(s, t)^{1/p}}$$

$$\rho^{(k)}_{p-\omega;[s, t]}(x, y) := \sup_{s \leq u < v \leq t} \frac{|\pi_k(x_{u,v} - y_{u,v})|}{\omega(u, v)^{k/p}},$$

$$\rho_{p-\omega;[s, t]}(x, y) := \max_{k=1, \ldots, |p|} \rho^{(k)}_{p-\omega;[s, t]}(x, y)$$

$$d^{(k)}_{p-\text{var};[s, t]}(x, y) := \sup_{(t_i) \subset [s, t]} \left( \sum_i |\pi_k(x_{t_i, t_{i+1}} - y_{t_i, t_{i+1}})|^{p/k} \right)^{k/p}$$

$$\rho_{p-\text{var};[s, t]}(x, y) := \max_{k=1, \ldots, |p|} \rho^{(k)}_{p-\text{var};[s, t]}(x, y).$$

Note that the metrics $d_{p-\text{var}}$ and $\rho_{p-\text{var}}$ both induce the same topology on the respective rough paths spaces, as do the metrics $d_{\frac{1}{2}-H^\text{Hol}}$ and $\rho_{p-\omega;[s, t]}$ with the choice $\omega(s, t) = |t - s|$; cf. [FV10b] for more details.

We now recall the basic facts about Gaussian rough paths. If $I = [a, b]$ is an interval, a *dissection* of $I$ is a finite subset of points of the form $\{a = t_0 < \ldots < t_m = b\}$. The family of all dissections of $I$ is denoted by $D(I)$. Let $I \subset \mathbb{R}$ be an interval and $A = [a, b] \times [c, d] \subset I \times I$ be a rectangle. If $f : I \times I \to V$ is a function, mapping into a normed vector space $V$, we define the *rectangular increment* $f(A)$ by setting
Definition 24. Let \( p \geq 1 \) and \( f : I \times I \to V \). For \([s, t] \times [u, v] \subset I \times I\), set

\[
V_p(f; [s, t] \times [u, v]) := \left( \sup_{(t_i) \in D([s, t])} \sum_{t_i, t_{i+1}} f \left( \frac{t_{i+1}}{t_i}, \frac{t_{i+1}}{t_{i+1}} \right) \right)^{\frac{1}{p}}.
\]

If \( V_p(f; I \times I) < \infty \), we say that \( f \) has finite \((2D)\) \( p \)-variation. Similarly, we set

\[
V_{1,p}(f; [s, t] \times [u, v]) := \left( \sup_{(t_i) \in D([s, t])} \left\{ \sum_{t_i, t_{i+1}} \left( \sum_{t_j, t_{j+1}} f \left( \frac{t_{j+1}}{t_j}, \frac{t_{j+1}}{t_{j+1}} \right) \right)^p \right\}^{\frac{1}{p}} \right).
\]

and call this the \((\text{mixed, right})\) \((1,p)\)-variation of \( f \).

Let \( X = (X^1, \ldots, X^d) : [0, T] \to \mathbb{R}^d \) be a centered Gaussian process. Then the covariance function \( R_X(s, t) := \text{Cov}_X(s, t) = E(X_s \otimes X_t) \) is a map \( R_X : I \times I \to \mathbb{R}^{d \times d} \). Next, we cite the fundamental existence result about Gaussian rough paths. For a proof, cf. [FV10a] or [FV10b] Chapter 15.

Theorem 25. Let \( X : [0, T] \to \mathbb{R}^d \) be a centered Gaussian process with continuous sample paths and independent components. Assume that there is a \( \rho \in [1, 2) \) such that \( V_p(R_X; [0, T]^2) < \infty \). Then \( X \) admits a lift \( \pi(X) \) to a process whose sample paths are geometric \( p \)-rough paths for any \( p > 2\rho \), i.e. with sample paths in \( C^{0,p-\text{var}}_0([0, T], G^p(\mathbb{R}^d)) \) and \( \pi_1(X_s, t) = X_t - X_s \) for any \( s < t \). \( X \) is a natural lift of \( X \) in the sense that if \( X^h \) is a suitable approximation of \( X \) (cf. [FV10b] chapter 15) or section 2.3 for the exact definition), then

\[
|d_{p-\text{var}}(S_{[t]}(X^h), X)|_{L^r} \to 0
\]

for \( h \to 0 \) and all \( r \geq 1 \). Moreover, if \( V_p(R_X; [s, t]^2) \lesssim |t - s|^\frac{1}{p} \) holds for all \( s < t \), then the sample paths of \( X \) can be lifted to \( \frac{1}{p} \)-Hölder rough paths and the \( L^r \)-convergence holds for the \( d_{\frac{1}{p}} \)-Hölder metric.

Remark 26. The condition \( V_p(R_X; [s, t]^2) \lesssim |t - s|^\frac{1}{p} \) can be checked for many Gaussian processes. It holds, for instance, for Brownian motion, the Ornstein-Uhlenbeck process and the Brownian bridge with the choice \( \rho = 1 \). Moreover, it holds for the fractional Brownian motion \( B^H \) with \( \frac{1}{2p} = H \), where \( H \) denotes the Hurst parameter, even in the stronger form of mixed \((1, p)\)-variation, cf. [FGR13] Theorem 6. Theorem 25 implies that \( B^H \) has a lift in the sense of Theorem 25 as long as \( H > \frac{1}{4} \).
